APPROPRIATE USE CRITERIA

Nuclear Cardiology

James E. Udelson, Vasken Dilsizian,
and Robert O. Bonow

The American College of Cardiology Foundation, the American Society of Nuclear Cardiology, and other organizations have published appropriate use criteria (AUC) for radionuclide imaging as a guide for clinicians to the appropriateness of ordering an imaging procedure in various clinical scenarios. The initial AUC for radionuclide imaging were published in 2005¹ and updated in 2009.² The AUC are meant to complement and to incorporate “disease-based” guideline recommendations as much as possible while acknowledging that many clinical scenarios faced by clinicians do not fit neatly into the evidence base from the published literature on which more formal guidelines are built. This approach has become the primary mechanism for rating procedures and tests such as radionuclide imaging

and echocardiography while guidelines continue to be developed for clinical disease states and syndromes.

After development of the clinical indications to be rated, a panel of professionals with a broad array of expertise (i.e., not just imaging experts) rates the “appropriateness” of radionuclide imaging in each scenario, using the following definition: “An appropriate imaging study is one in which the expected incremental information, combined with clinical judgment, exceeds the expected negative consequences by a sufficiently wide margin for a specific indication that the procedure is generally considered acceptable care and a reasonable approach for the indication.”¹ Rating scores are made on a scale of 1 to 9, in which a score of 9 indicates a highly appropriate use of testing. Using an iterative modified Delphi exercise process, with predefined rules, a final rating score is established for each indication, according to the following categories: A, scores 7 to 9, an *appropriate* test for the specific indication (the test is generally acceptable and is a reasonable approach for the indication); U, scores 4 to 6, *uncertain* for the specific indication (the test may be generally acceptable and may be a reasonable approach for the indication); and I, scores 1 to 3, an *inappropriate* test for that indication (the test is not generally acceptable and is not a reasonable approach for the indication) (Table 16G-1).¹

TABLE 16G-1 Appropriate Use Criteria for Nuclear Cardiology

Detection of CAD: Symptomatic	
INDICATION	APPROPRIATE USE SCORE (1-9)
Evaluation of Ischemic Equivalent (NonAcute)	
1. Low pretest probability of CAD ECG interpretable <i>and</i> able to exercise	I (3)
2. Low pretest probability of CAD ECG uninterpretable <i>or</i> unable to exercise	A (7)
3. Intermediate pretest probability of CAD ECG interpretable <i>and</i> able to exercise	A (7)
4. Intermediate pretest probability of CAD ECG uninterpretable <i>or</i> unable to exercise	A (9)
5. High pretest probability of CAD Regardless of ECG interpretability and ability to exercise	A (8)
Acute Chest Pain	
6. Possible ACS ECG—no ischemic changes or with LBBB or electronically ventricular paced rhythm Low-risk TIMI score Peak troponin: borderline, equivocal, minimally elevated	A (8)
7. Possible ACS ECG—no ischemic changes or with LBBB or electronically ventricular paced rhythm High-risk TIMI score Peak troponin: borderline, equivocal, minimally elevated	A (7)
8. Possible ACS ECG—no ischemic changes or with LBBB or electronically ventricular paced rhythm Low-risk TIMI score Negative peak troponin levels	A (8)
9. Possible ACS ECG—no ischemic changes or with LBBB or electronically ventricular paced rhythm High-risk TIMI score Negative peak troponin levels	A (8)
10. Definite ACS	I (1)
Acute Chest Pain (Rest Imaging Only)	
11. Possible ACS ECG—no ischemic changes or with LBBB or electronically ventricular paced rhythm Initial troponin negative Recent or ongoing chest pain	A (7)

TABLE 16G-1 Appropriate Use Criteria for Nuclear Cardiology—cont'd
Detection of CAD/Risk Assessment Without Ischemic Equivalent

INDICATION		APPROPRIATE USE SCORE (1-9)
Asymptomatic		
12.	Low CHD risk (ATP III risk criteria)	I (1)
13.	Intermediate CHD risk (ATP III risk criteria) ECG interpretable	I (3)
14.	Intermediate CHD risk (ATP III risk criteria) ECG uninterpretable	U (5)
15.	High CHD risk (ATP III risk criteria)	A (7)
New-Onset or Newly Diagnosed Heart Failure with LV Systolic Dysfunction Without Ischemic Equivalent		
16.	No previous CAD evaluation <i>and</i> no coronary angiography	A (8)
New-Onset Atrial Fibrillation		
17.	Part of evaluation when etiology unclear	U (6)
Ventricular Tachycardia		
18.	Low CHD risk (ATP III risk criteria)	A (7)
19.	Intermediate or high CHD risk (ATP III risk criteria)	A (8)
Syncope		
20.	Low CHD risk (ATP III risk criteria)	I (3)
21.	Intermediate or high CHD risk (ATP III risk criteria)	A (7)
Elevated Troponin		
22.	Troponin elevation without additional evidence of ACS	A (7)

Risk Assessment with Previous Test Results and/or Known Chronic Stable CAD

INDICATION		APPROPRIATE USE SCORE (1-9)
Asymptomatic or Stable Symptoms		
Normal Previous Stress Imaging Study		
23.	Low CHD risk (ATP III risk criteria) Last stress imaging study done <2 years ago	I (1)
24.	Intermediate to high CHD risk (ATP III risk criteria) Last stress imaging study done <2 years ago	I (3)
25.	Low CHD risk (ATP III risk criteria) Last stress imaging study done ≥2 years ago	I (3)
26.	Intermediate to high CHD risk (ATP III risk criteria) Last stress imaging study done ≥2 years ago	U (6)
Abnormal Coronary Angiography or Abnormal Previous Stress Imaging Study, No Previous Revascularization		
27.	Known CAD on coronary angiography or prior abnormal stress imaging study Last stress imaging study done <2 years ago	I (3)
28.	Known CAD on coronary angiography or prior abnormal stress imaging study Last stress imaging study done ≥2 years ago	U (5)
Previous Noninvasive Evaluation		
29.	Equivocal, borderline, or discordant stress testing in which obstructive CAD remains a concern	A (8)
New or Worsening Symptoms		
30.	Abnormal coronary angiography or abnormal previous stress imaging study	A (9)
31.	Normal coronary angiography or normal previous stress imaging study	U (6)
Coronary Angiography (Invasive or Noninvasive)		
32.	Coronary stenosis or anatomic abnormality of uncertain significance	A (9)
Asymptomatic		
Previous Coronary Calcium Agatston Score		
33.	Agatston score less than 100	I (2)
34.	Low to intermediate CHD risk Agatston score between 100 and 400	U (5)

ATP III = Adult Treatment Panel III; CHD = coronary heart disease; ERNA = equilibrium radionuclide angiography; HF = heart failure; MET = [estimated] metabolic equivalents of exercise; RNA = radionuclide angiography; UA/NSTEMI = unstable angina/non-ST elevation myocardial infarction.

From Hendel RC, Berman DS, Di Carli MF, et al: ACCF/ASNC/ACR/AHA/ASE/SCCT/SCMR/SNM 2009 appropriate use criteria for cardiac radionuclide imaging: A report of the American College of Cardiology Foundation Appropriate Use Criteria Task Force, the American Society of Nuclear Cardiology, the American College of Radiology, the American Heart Association, the American Society of Echocardiography, the Society of Cardiovascular Computed Tomography, the Society for Cardiovascular Magnetic Resonance, and the Society of Nuclear Medicine. *J Am Coll Cardiol* 3:2201, 2009.

As an example, among stable outpatients with chest pain syndromes, those with an intermediate or high pretest likelihood of coronary artery disease are thought to be appropriate candidates for nuclear imaging along with stress testing, whereas those with a low pretest likelihood who can exercise are not. Patients within 1 year of successful percutaneous coronary intervention (PCI) who had symptoms before PCI and remain asymptomatic after PCI are thought to be inappropriate candidates for single photon emission computed tomography (SPECT) (i.e., routine “surveillance” stress imaging). It is likely that third party payers will use these criteria as a basis for reimbursement decisions at some point in the future.

The current methodology³ has changed the AUC nomenclature such that the term “inappropriate” for ratings of 1 to 3 is now “rarely appropriate,” and ratings of 4 to 6 are now termed “may be appropriate.” Ratings of 7 to 9 remain “appropriate.” However, the AUC for nuclear cardiology² have not yet been updated to reflect this change in terminology. The recent AUC documents for multimodality imaging in stable ischemic heart disease and heart failure^{4,5} do conform to the updated terminology and provide criteria for use of echocardiography in these conditions relative to the applications of the other imaging modalities (see Appropriate Use Criteria: Multimodality Imaging in Stable Ischemic Heart Disease and Heart Failure in [Chapter 20](#)).

APPROPRIATE USE CRITERIA, 338

With excellent spatial and temporal resolution, unrestricted tomographic fields, and no exposure to ionizing radiation, cardiac magnetic resonance imaging (CMR) provides morphologic and functional information relevant to a broad array of cardiovascular diseases. This chapter reviews the current evidence for use of CMR in diagnosing and treating cardiovascular disease.

BASIC PRINCIPLES OF MAGNETIC RESONANCE IMAGING

The Magnetic Field and the Gradient Coil System

Magnetic resonance imaging (MRI) is based on imaging of protons within the abundant hydrogen atoms in the human body. The hydrogen protons behave like tiny magnets. When a patient is placed inside the CMR scanner within a static magnetic field (called B_0), spins either align with or opposite of the main direction of B_0 . The summation of the aligned and opposing spins forms a net magnetization vector that aligns along the longitudinal axis (z axis) of the magnet at static state before deposition of any radiofrequency (RF) pulse. B_0 is designed to have the same strength along each of the three orthogonal directions (designated x, y, and z) inside the CMR bore; thus it is a *homogeneous magnetic field*. The homogeneous B_0 is fine-tuned by the computer-controlled adjustments of currents in small coils mounted within the magnet (known as *active shimming*). Apart from lining up with B_0 , spins also precess (wobble about the axis of the B_0 field) at a frequency ω_0 (the *Larmor frequency*) proportional to B_0 as described by the following equation: $\omega_0 = \gamma B_0$, where γ is the *gyromagnetic ratio* (a constant for hydrogen for a given field strength). In order to introduce a system of spatial address of the Larmor frequency, three orthogonal sets of gradient coils are placed so that a slight linear alteration in the strength of B_0 can be created in each of the x, y, and z directions. As a result, magnetic spins precess at frequencies according to their locations along each of the three orthogonal axes, and they can be selectively excited by specific radiofrequency pulses.¹

Generation of Magnetic Resonance Signal, Signal Contrast, and Image Formation

In order to create a magnetic resonance image, an RF pulse with a frequency matched to the Larmor frequency of the magnetic spins will excite magnetic spins of interest to a higher energy state, which

leads to transition of the net magnetization vector from the z axis onto the x-y plane. The extent to which the magnetization vector is tipped away from the direction of B_0 (z axis) defines the *flip angle*, reflects the amount of energy deposition in tissue, and is a function of the strength and duration of the RF pulse. The magnitude of the vector onto the x-y plane will determine the amount of signal generated, which is received by a set of surface coils. For the purpose of imaging a specific slice plane through the body, the magnetic gradient causes a spread of Larmor frequencies perpendicular to a prescribed slice plane. The RF pulse will then excite only the slice plane with magnetic spins precessing at frequencies matching the frequency bandwidth of the RF pulse.

The absorbed electromagnetic energy will be released by two coexisting mechanisms, longitudinal magnetization recovery and transverse magnetization decay. *Longitudinal magnetization recovery* corresponds to the exponential rate of recovery of the longitudinal component (z-direction) of the magnetization vector, characterized by a time constant, T1, which is defined as the time to recover 63% of the original longitudinal magnetization vector. T1 is a physical characteristic of tissue and is affected by the field strength of the scanner, with values progressively greater (longer times) at higher field strengths (in Tesla units). T1 characterization therefore allows generation of images that reflect the differences of T1 between tissue types. A T1-weighted scan will keep the time between delivery of two successive flip angles (repetition time) short, so tissues with different T1 values will demonstrate different signal intensity as they follow a T1 recovery. The *transverse magnetization decay* results from interaction between neighboring spins (spin-spin interaction) leading to exponential loss of the transverse component of the net magnetization vector, defined by the time constant T2. T2 also is a tissue-specific parameter and is defined as the time to lose 63% of the transverse magnetization. Unlike T1 values, T2 values are less related to the field strength of the scanner. The choice of signal contrast weighting of the imaging method is dictated in part by the physiologic characteristics of the tissue being studied. For qualitative interpretation, signal enhancement (from T1 effects) is in general preferred over darkening (T2*) (see explanation further on) effects, so most pulse sequences used in CMR are relative T1-weighted signal-enhancing techniques. T2-weighted and T2*-weighted CMR are primarily used for imaging of myocardial edema and iron content, respectively. With the application of magnetic field gradients in any of the three orthogonal directions, the magnetic resonance signal can carry spatial localization information, produced by encoding

steps known as slice select, phase encoding, and frequency encoding. All relevant information of the magnetic resonance signal is stored in a data matrix called the *k-space*, which will undergo two-dimensional inverse Fourier transformation to form an image.

CONTRAST AGENTS IN CARDIAC MAGNETIC RESONANCE

Currently only gadolinium-based contrast agents (GBCAs) are used in clinical practice. When injected as an intravenous bolus, a GBCA takes 15 to 30 seconds for transit through the cardiac chambers and blood vessels (*first-pass phase*) before it diffuses into the extracellular space. At approximately 10 to 15 minutes after injection, a transient equilibrium between contrast washing-in into the extracellular space and washing-out to the blood pool is reached. Myocardial perfusion CMR and most magnetic resonance angiography (MRA) examinations are performed during the first-pass phase, whereas *late gadolinium enhancement* (LGE) images are obtained during the equilibrium phase. Several GBCAs are commercially available in the United States; however, their use in CMR imaging is considered off-label. Mild reactions from GBCAs occur in approximately 1% of patients receiving these agents, but severe or anaphylactic reactions are very rare. All GBCAs are chelated to make the compounds nontoxic and to allow renal excretion. Exposure to the nonchelated component of GBCAs (Gd^{3+}) has been associated with a rare condition known as nephrogenic systemic fibrosis (NSF), which is an interstitial inflammatory reaction that leads to severe skin induration, contracture of the extremities, fibrosis of internal organs, and even death. Risk factors for development of NSF include high-dose (>0.1 mmol/kg) GBCA regimens with estimated glomerular filtration rate (eGFR) less than 30 mL/min/1.73 m², need for hemodialysis, an eGFR less than 15 mL/min/1.73 m², use of gadodiamine (Omniscan, General Electric Healthcare, Chalfont St. Giles, Buckinghamshire, United Kingdom), acute renal failure, and presence of concurrent proinflammatory events. With the use of weight-based dosing and pretest screening, recent data suggest that NSF is now extremely rare. Previously, an incidence of 0.02% in 83,121 patients exposed to GBCAs over 10 years was noted; however, with current eGFR screening guidelines that have been widely practiced since 2006, a near-zero incidence has been reported.²

TECHNICAL ASPECTS OF CARDIAC MAGNETIC RESONANCE PULSE SEQUENCES

CMR uses a range of strategies to overcome technical difficulties caused by cardiac, respiratory, and blood flow motion. Synchronized gating to the electrocardiogram (ECG) is routinely performed. Cardiac gating can be either prospective (triggering by an ECG waveform followed by a fixed period of acquisition during all cardiac cycles) or retrospective (continuous data acquisition with subsequent reconstruction based on ECG timing). For cine imaging, retrospective gating is preferred because it covers the entire cardiac cycle and is less prone to artifacts. To reduce blurring from cardiac motion, many CMR techniques fractionate the data for an image to acquire data only within a narrow window of the cardiac cycle (segmented approach). Currently, patient breath-holding remains the most common method to contain respiratory motion during CMR data acquisition, although navigator-based techniques (tracking of diaphragmatic motion to control respiratory motions) and respiratory motion averaging are options in some pulse sequences. Finally, by rapidly acquiring data of an entire image within a cardiac cycle, single-shot imaging and real-time cine imaging (continuous acquisition of single-shot images) can overcome both respiratory and cardiac motions, but at the expense of reduced temporal and spatial resolution. [Table e17-1](#) shows a summary of the most common clinical CMR pulse sequence techniques at our center. Minor variations exist in these parameters between centers and vendors. CMR uses bright-blood cine imaging or dark-blood fast spin-echo (FSE) imaging to assess cardiac morphology and structure. Cine CMR is the modality that serves as a reference standard for quantifying ventricular volumes. Among the cine techniques, cine steady-state free precession (SSFP) is the technique of choice. It can acquire a cine movie at a high temporal resolution of 30 to 45 milliseconds during a breath-hold of less than 10 seconds, thereby capturing the whole heart in motion volumetrically in 3 to 5 minutes ([Fig. 17-1](#); Video 17-1). For dark-blood techniques, T1-weighted FSE is used for assessing morphology of cardiac chambers, vascular structures, and pericardium and for imaging of fat ([Fig. 17-2](#)). T2-weighted FSE with fat suppression is used for imaging of myocardial edema occurring as a result of ischemia, infection, or infiltration. Three main techniques have been developed to quantify

FIGURE 17-1 Cine CMR imaging of myocardial infarction (MI) complications. The patient was a 67-year-old woman who presented 2 months after an inferior MI complicated by a ventricular septal defect. Cine imaging demonstrates inferior akinesis, intracavitary thrombus (black arrow), and residual flow across the defect (white arrow).

intramyocardial motion: myocardial grid or line tagging, phase contrast velocity mapping of myocardial motion, and displacement encoding with stimulated echoes (DENSE). Tagging assesses myocardial strain by marking the myocardium with parallel dark lines or a grid so that myocardial deformation can be visualized or quantified. Circumferential and radial strain also can be calculated and displayed with a color-coded scale. Although myocardial tagging is the most widely available, phase contrast velocity mapping and DENSE techniques can be completed at higher spatial resolution.

T1-weighted imaging techniques such as LGE imaging can detect accumulation of GBCA into the extracellular compartment of the myocardium secondary to infarction, infiltration, or fibrosis. LGE is detected 5 to 15 minutes after an intravenous injection of GBCA (0.1 to 0.2 mmol/kg) (hence the designation “late”). LGE data can be captured in two- or three-dimensional representation. Several technical improvements in LGE imaging have emerged. Phase-sensitive inversion recovery (PSIR) reference imaging incorporates the phase polarity information that enhances myocardial tissue contrast. Single-shot LGE imaging offers an option to overcome motion when cardiac gating or patient breath-holding is not possible. Navigator-guided LGE eliminates the need for breath-holding and allows three-dimensional acquisition with in-plane resolution below 1 mm ([Fig. 17-3](#); Video 17-2). CMR perfusion imaging examines the first-pass transit of an intravenous bolus of GBCA as it travels through the coronary circulation. Several perfusion techniques are available, which are fast bright-blood gradient-echo imaging sequences in which three to five short-axis slices of the heart are acquired every cardiac cycle, during the injection of a GBCA bolus. Gadolinium provides strong signal enhancement in well-perfused regions, compared with hypoenhancement (dark regions) in poorly perfused myocardium. At a spatial resolution of approximately 2 mm in plane, CMR perfusion imaging can provide information of myocardial blood flow at the endocardial/epicardial or at a segmental level ([Fig. 17-4](#); Video 17-3). Dynamic three-dimensional perfusion imaging can provide greater myocardial coverage and improved image quality and has shown promising preliminary clinical results.³ T2-weighted imaging detects myocardial edema, from ischemic injury or inflammation, and it has been shown to have high correlation to the area at risk after acute myocardial infarction (MI). It also complements LGE imaging in determining the chronicity of an MI and allowing for accurate measurement of *salvageable myocardium*. The pulse sequence options for T2-weighted imaging include black-blood short T1 inversion recovery (STIR) FSE and the newer SSFP-type methods,⁴ and their merits are listed in [Table e17-1](#). T2* is a transverse relaxation parameter sensitive to tissue iron content. T2* imaging is a well-validated method for measuring tissue iron content. A T2* less than 20 milliseconds (value for normal myocardium, approximately 40 to 50 milliseconds) is diagnostic of myocardial iron overload, and a T2* less than 10 milliseconds is evidence of severe iron overload⁵ ([Fig. 17-5](#); Video 17-4). Despite challenges posed by small luminal sizes and cardiac and respiratory motions,

TABLE e17-1 Summary of Common Clinical Cardiac Magnetic Resonance Pulse Sequence Techniques at Brigham and Women's Hospital

TECHNIQUE	PULSE SEQUENCE OPTIONS	DARK-/BRIGHT-BLOOD	CONTRAST WEIGHTING	TYPICAL IN-PLANE SPATIAL/TEMPORAL RESOLUTIONS AND OTHER IMAGING PARAMETERS		BREATH-HOLD REQUIRED	GADOLINIUM CONTRAST REQUIRED	RELATIVE MERITS OF THE PULSE SEQUENCE OPTIONS	IMAGE EXAMPLE
				1.5-2.5 mm/30-45 msec per phase	• Adjust number of lines of k-space per cardiac cycle (segments) to balance temporal resolution with duration of patient breath-holds				
Cine cardiac structure and ventricular function	Cine SSFP* Cine FGRE Real-time cine SSFP	Bright	T2W/T1W for cine SSFP and real-time cine SSFP; T1W for FGRE			Yes for ECG-gated cine SSFP and FGRE No for real-time cine	No	Cine SSFP has higher SNR and CNR (between endomyocardium and blood) than FGRE but is sensitive to field inhomogeneity (especially at 3T), giving rise to banding artifact FGRE has weaker endocardial definition than cine SSFP but is an alternative with severe artifact in cine SSFP Real-time cine SSFP: use in patients with significant arrhythmia or difficulty breath-holding; it has the lowest spatial and temporal resolutions	
Quantitative regional myocardial strain	Myocardial tagging (newer but less widely available techniques for regional strain exist, (see text))	Bright	T1W	• Tag spacing 5-10 mm • Temporal resolution ~50 msec		Yes	No	Tissue tracking quantitation of intramyocardial motion Disadvantages: fading of tag lines near end of cardiac cycle and time-consuming strain analysis (postprocessing)	
Structure, morphology, and fat imaging	Standard FSE* Single-shot (SS) FSE (or HASTE)	Dark	T1W ± fat suppression	0.8-1.5 mm every cardiac cycle		Yes for standard FSE No for SS FSE	No	Standard FSE has better image quality but relatively long scan time Fat suppression can be achieved by fat saturation pulse (more specific) or by suppressing tissues with short T1 (a technique known as STIR, which is less specific for fat). SS FSE covers the whole heart quickly and is useful in patients with arrhythmia or limited breath-holding

Simultaneous high-resolution imaging of myocardial infarction and coronary stenosis in a 48-year-old man with three-vessel coronary artery disease. A, Proximal right coronary artery stenosis. B, Left ventricular scar. Images are acquired using a combined three-dimensional coronary/late gadolinium enhancement imaging sequence with isotropic spatial resolution of 1.3 cubic mm.

VIDEO 17-3

CMR imaging of ischemia and infarct extent. Movie display of stress perfusion (left) and late gadolinium enhancement imaging of infarction (right). The patient was a 59-year-old obese man with dyspnea on exertion. **Left**, First pass resting perfusion reveals a severe defect in the inferolateral wall (*arrow*). **Right**, Late gadolinium enhancement imaging demonstrates two foci of previously unrecognized infarcted myocardium. Subsequent coronary angiography revealed severe stenoses in the left circumflex and right coronary arteries. Images of ischemia and infarction can be superimposed and compared qualitatively and quantitatively.

VIDEO 17-4

Quantitation of myocardial iron content. Short-axis T2* fast-gradient echo images of a 41-year-old man with systemic hemochromatosis presented with exertional dyspnea. T2* imaging shown here represents a series of 8 images with progressively longer echo time (**A**). As the echo time of images increased, there was rapid signal reduction of the myocardium (myocardium turned dark rapidly), suggestive of high iron content in the myocardium. Quantitative measurement resulted in a T2* of 6.6 msec (T2* of <20 msec in a patient with unexplained cardiomyopathy is consistent with iron overload).

FIGURE 17-2 Lipomatous hypertrophy of the interatrial septum. The patient was a 78-year-old woman who was referred for evaluation of a right atrial mass. **A**, T1-weighted turbo spin echo image in the axial plane shows extensive thickening of the right side of the interatrial septum and of the right atrial free wall (arrows), sparing the fossa ovalis (arrowhead). The high signal intensity is suggestive of a right atrial lipoma or lipomatous hypertrophy of the atrial septum. **B**, After application of fat saturation in the same plane orientation, the signal from the right atrial mass is completely nulled (asterisk), confirming its lipomatous nature and the diagnosis of lipomatous hypertrophy of the atrial septum. LA = left atrium; RA = right atrium. (Courtesy François-Pierre Mongeon, MD, SM, FRCPC, Montreal Heart Institute, Université de Montréal, Montreal, Quebec, Canada.)

FIGURE 17-3 Simultaneous high-resolution imaging of MI and coronary stenosis in a 48-year-old man with three-vessel coronary artery disease. **A**, Proximal right coronary artery stenosis (arrow). **B**, Left ventricular scar (arrows). Images were acquired using a combined three-dimensional coronary/late gadolinium enhancement imaging sequence with isotropic spatial resolution of 1.3 mm³. (Courtesy Reza Nezafat, PhD, Beth Israel Deaconess Medical Center, Boston.)

FIGURE 17-4 CMR imaging of ischemia and infarct extent in a 59-year-old obese man with dyspnea on exertion. **A**, First-pass resting perfusion image reveals a severe defect in the inferolateral wall (arrow). **B**, Late gadolinium enhancement demonstrates two foci of previously unrecognized infarcted myocardium (arrows). Subsequent coronary angiography revealed severe stenoses in the left circumflex and right coronary arteries. Images of ischemia and infarction can be superimposed and compared qualitatively and quantitatively.

FIGURE 17-5 Quantitation of myocardial iron content in a 41-year-old man with systemic hemochromatosis and exertional dyspnea. T2* imaging (A) demonstrated abnormal T2 relaxation (B), suggestive of cardiac iron overload.

FIGURE 17-6 Coronary MRA. Normal coronary anatomy is demonstrated on two-dimensional images (A, B) and on three-dimensional reconstruction (C). LAD = left anterior descending coronary artery; LCX = left circumflex coronary artery, RCA = right coronary artery.

technical advances in coronary MRA imaging have favored the use of whole-heart three-dimensional acquisition (with or without navigator guidance), with promising preliminary clinical results⁶ (Fig. 17-6). Similar to Doppler echocardiography (see Chapter 14), phase contrast imaging allows quantitation of velocities of blood flow and myocardial motion and intravascular flow rates. Parallel imaging is a family of techniques that speeds up CMR (k-space) data acquisition by combining information obtained separately from each element of the surface receiver coils. Incorporating parallel imaging can reduce acquisition time, improve temporal resolution, or even eliminate certain artifacts. The main disadvantage of parallel imaging is a reduction in signal-to-noise ratio resulting from undersampling of the k-space data.

PATIENT SAFETY IN CARDIAC MAGNETIC RESONANCE

Clinical CMR scanners generate strong magnetic fields. The magnetic field component can be disabled with difficulty by evaporating the cooling liquid helium to the outside environment, but this action carries significant risk and is associated with high restoration costs. Common implants hazardous in CMR scanning include cochlear implants, neurostimulators, hydrocephalus shunts, metal-containing ocular implants, pacing wires, and metallic cerebral aneurysm clips. A full list is available at www.mrisafety.com (the official website for the Institute for Magnetic Resonance Safety, Education, and Research).

Sternal wires, mechanical heart valves, annuloplasty rings, coronary stents, nonmetallic catheters, and orthopedic or dental implants are safe. Most claustrophobic patients can be managed with oral sedation alone or the use of a scanner with large bore size.

The risks associated with performing MRI in patients with a pacemaker or an implantable cardioverter-defibrillator (ICD) (see Chapter 36) include generation of an electrical current from the metallic hardware, device movement induced by the magnetic field, inappropriate discharging and sensing, and heating as a result of the “antenna effect.” However, a number of experienced centers have reported safety in performing CMR in a controlled setting in patients who have recent pacemaker models and are not pacemaker-dependent. The first pacemaker designed to allow MRI scanning has been approved by the U.S. Food and Drug Administration (FDA), but imaging over the chest and neck region currently is not recommended.

CARDIAC MAGNETIC RESONANCE ASSESSMENT OF SPECIFIC DISORDERS AND CONDITIONS

Discussed in this section are clinical applications of CMR. Table e17-2 summarizes the CMR protocols, by study indications, used at our center. A detailed description of CMR protocols endorsed by the Society of Cardiovascular Magnetic Resonance (SCMR) can be found

TABLE e17-2 Typical Cardiac Magnetic Resonance Protocols at Brigham and Women's Hospital

STUDY INDICATION(S)	TECHNIQUES OF HIGH RELEVANCE	TYPICAL SCAN PLANES	OPTIONAL TECHNIQUES
Myocardial viability for benefit from coronary revascularization	Cine cardiac structure/function Low-dose dobutamine cine (may depend on local expertise) Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations	Stress myocardial perfusion Phase contrast for coexisting valvular heart disease Imaging for cardiac thrombus
Myocardial ischemia Vasodilating stress Dobutamine stress	Cine cardiac structure/function Myocardial perfusion at peak vasodilating stress and at rest LGE imaging for myocardial scar Cine function during escalating stages of dobutamine infusion \pm atropine LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations 3 short-axis and 2 or 3 long-axis locations for stress cine	Myocardial perfusion during dobutamine stress
Acute myocardial infarction	Cine cardiac structure/function Myocardial edema imaging Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations	Imaging for cardiac thrombus and microvascular obstruction (no-reflow)
Detecting ACS or other causes of myocardial injury	Cine cardiac structure/function Myocardial edema imaging Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations	Stress myocardial perfusion
Assessing the etiology of an undiagnosed cardiomyopathy or a specific cardiomyopathy	Cine cardiac structure/function Myocardial perfusion at rest Myocardial edema imaging (if acute myocarditis, ACS, or infiltrative CMP suspected) LGE imaging for myocardial scar	Short-axis stack and selected long-axis or axial locations	Myocardial and hepatic iron content (if cardiac hemosiderosis suspected) Stress myocardial perfusion (if CAD suspected) FSE with and without fat suppression (if ARVC suspected) Phase contrast flow imaging (if outflow obstruction suspected in HCM) Myocardial T1 quantitation (amyloidosis)
Pericardial disease	Cine cardiac structure/function T1W FSE without fat suppression to assess pericardium (low-intensity linear structure that lies between high-intensity mediastinal and epicardial fat) Myocardial edema imaging (if acute myocarditis, ACS, or infiltrative CMP suspected) LGE imaging for myocardial scar	Short-axis stack and selected long-axis or axial/oblique locations	Myocardial tagging to assess perimyocardial adhesions in region of reduced strain Imaging for sizes of the vena cavae Real-time cine SSFP (to see septal motion) and phase contrast flow across the tricuspid valve for pericardial constriction. T1W and T2W techniques to assess fluid content of significant pericardial effusion: transudative effusion is gray or dark on T1W and bright on T2W images; exudative effusion is bright and subacute hemorrhage is inhomogeneous on T1W images
Valvular heart disease	Cine cardiac structure/function Phase contrast flows of the dysfunctional valve of interest (Note: use appropriate velocity-encoding strengths to obtain peak velocity [valvular stenosis] and forward/regurgitant flows [valvular insufficiency]) Imaging of the great vessels (FSE, MRA, or others)	Short-axis stack and selected long-axis or axial/oblique locations	LGE for myocardial scar (e.g., severe aortic stenosis)
Cardiac mass/thrombus	Cine cardiac structure and function (size, attachment, and motion pattern of the mass). T1W imaging before and after contrast to assess vascularity of the mass FSE to assess fat content and structure. T2W FSE to look for tissue edema or simple cyst	Short-axis stack and selected long-axis or axial/oblique locations	EGE or LGE with long inversion time to assess for thrombus First-pass perfusion to assess mass with high vascularity LGE to detect necrosis.
CMR for left atrial mapping and pulmonary vein ablation	Cine cardiac structure/function 3D MRA imaging of the left atrial volume and pulmonary veins	Short-axis stack and selected long-axis Coronal 3D locations for MRA	Phase contrast imaging prescribed as cross sections of the origins of the pulmonary veins from the coronal MRA images (Note: Use encoding velocity strength of 30 cm/sec for normal flow and increase if pulmonary stenosis suspected or aliasing detected) High-resolution LGE imaging of the left atrial scar (with navigator guidance) has been reported by experienced centers in patients who had undergone radiofrequency ablation of the left atrium

ACS = acute coronary syndrome; CMP = cardiomyopathy; EGE = early gadolinium enhancement; FGRE = fast gradient recalled echo; HCM = hypertrophic obstructive cardiomyopathy; 3D = three-dimensional; T1W = T1-weighted; T2W = T2-weighted.

at www.scmr.org.⁷ In addition, the SCMR has established reporting guidelines to provide a framework for enhancing communication with referring physicians.⁸

Coronary Artery Disease

Current CMR protocol for coronary artery disease (CAD) integrates cine imaging, T2-weighted edema imaging, myocardial perfusion at rest and stress, and LGE imaging of MI and provides a comprehensive evaluation of myocardial anatomy and physiology. Coronary MRA is done as a part of the examination in more experienced centers. As noted, [Table e17-2](#) summarizes the CMR protocols used in our center; the typical CMR findings are described in [Table e17-3](#).

Myocardial Infarction

LGE imaging currently is the most accurate noninvasive method for quantifying infarct size and morphology. Infarct size estimated by LGE imaging has been well validated against histologic pattern, and commercial software systems are available to perform infarct size quantitation. With an excellent spatial resolution of 1.5 to 2 mm and a high contrast-to-noise ratio, LGE imaging provides detection of subendocardial infarction beyond either single photon emission computed tomography (SPECT) or positron emission tomography (PET) imaging (see [Chapter 16](#)). The robustness of the LGE imaging across MRI models was demonstrated by a double-blinded multicenter randomized clinical trial in which LGE was shown to detect acute and chronic infarcts with a sensitivity of 99% and 94%, respectively.⁹ In the acute MI setting, when LGE imaging is performed early (within the first 5 minutes) after contrast injection, microvascular obstruction (no-reflow) can be seen as a dense hypoenhanced area surrounded by a bright region representing the infarct ([Fig. 17-7](#)). This noninvasive method for quantifying microvascular obstruction has been validated against angiographic parameters of microcirculatory flow. Recent reports have even demonstrated detection of myocardial hemorrhage as a result of reperfusion injury ([Fig. 17-8](#); [Video 17-5](#)). Acute right ventricular (RV) injury also can be detected at high sensitivity (see [Fig. 17-7](#)). Some evidence suggests that the

high spatial resolution and contrast-to-noise ratio of LGE imaging translate to useful patient prognostic information. For patients with acute MI, presence of either microvascular obstruction or acute RV injury has prognostic implication independent of left ventricular (LV) infarct size and LV ejection fraction (LVEF).¹⁰ In the nonacute setting, an infarct identified solely by LGE imaging in patients without a history or ECG evidence of MI or in patients with diabetes, is a strong predictor of adverse events, independent of common clinical risk markers.¹¹ The strength of LGE imaging in detecting clinically unrecognized MI has been extended to the population level. A recent large community-based cohort study demonstrated that LGE imaging detected a very high prevalence of unrecognized (and hence untreated) MI in older persons, which was missed by ECG. This group of patients experienced remarkably increased mortality risk.¹²

Several pilot studies demonstrated that infarct tissue heterogeneity quantified from LGE images may describe arrhythmogenic substrates that develop as the result of an MI. Schmidt and co-workers reported that monomorphic ventricular tachycardia during electrophysiologic studies was more strongly associated with infarct heterogeneity than with LVEF.¹³ Roes and colleagues found that infarct heterogeneity was a strong predictor of spontaneous ventricular arrhythmias necessitating appropriate ICD therapy in patients with MI.¹⁴ These findings are concordant with the observed association between infarct tissue heterogeneity and patient mortality in yet another study.¹⁵

Assessment of Myocardial Viability and Benefit from Coronary Revascularization

CMR allows multifaceted assessment of structure and physiology associated with myocardial viability. End-diastolic wall thickness alone has limited accuracy in predicting recovery of segmental function because the wall tissue may include irreversibly damaged myocardium and a thinned epicardial rim of viable myocardium. From early cine CMR studies, it has been shown that end-diastolic wall thickness of 5.5 mm or greater and dobutamine-induced systolic wall thickening of 2 mm or greater have excellent specificity and sensitivity in the prediction of segmental contractile recovery after revascularization (sensitivity, 89%; specificity, 94%). In a landmark paper by Kim and colleagues, the transmural extent of myocardial scar detected by LGE imaging was shown to accurately predict a progressive stepwise decrease in functional recovery despite successful coronary revascularization.¹⁶ This prediction of segmental functional recovery was especially strong in segments with resting akinesia or dyskinesia. Compared with dobutamine cine CMR, LGE imaging is easy to perform and interpret, and a 50% transmural cut-off point

FIGURE 17-7 Microvascular obstruction after acute myocardial infarction in a 63-year-old diabetic man presenting 18 hours after onset of chest pain with thrombus in the right coronary artery. LGE imaging demonstrates infarction in the inferior wall and the right ventricle (arrowheads), as well as microvascular obstruction in the inferior wall (arrow).

FIGURE 17-8 Myocardial rupture after acute inferior myocardial infarction in a 56-year-old man who presented with ventricular fibrillation. Focal dyskinesia of the inferolateral wall and low signal intensity on LGE imaging are suggestive of intramyocardial hemorrhage (arrow). Pseudoaneurysm with a contained myocardial rupture was diagnosed by CMR and surgically confirmed.

TABLE e17-3 Cardiac Magnetic Resonance Imaging (CMR) Findings That Differentiate Among Causes of Cardiomyopathy

STUDY INDICATION	CINE CARDIAC STRUCTURE/FUNCTION	MYOCARDIAL EDEMA	MYOCARDIAL PERFUSION	LGE IMAGING	ASSOCIATED CMR FINDINGS
Acute myocardial stunning	RWMA	Positive	Normal (at rest)	Normal	Stress perfusion may show perfusion defect during peak vasodilatation (if significant residual coronary stenosis exists) Coronary MRA may show luminal stenosis
Chronic myocardial hibernation	RWMA, regional wall thinning possible	Negative	Usually shows resting subendocardial perfusion defect in a coronary distribution	Normal	Stress perfusion shows larger extent of perfusion defect than at rest (reversible defect) in regions without LGE Intracavitary thrombus may exist in areas of stagnant flow
Acute MI	RWMA	Usually transmural bright region in the segments subtended by the infarct-related artery	Subendocardial perfusion at rest (given revascularization of infarct-related artery) represents no-reflow zone of infarction	Subendocardial or transmural LGE in a coronary distribution	Microvascular obstruction "no-reflow" may be seen by LGE or myocardial perfusion imaging Evidence of myocardial hemorrhage by T2 and T2* imaging has been described Intracavitary thrombus may exist in areas of stagnant flow
Chronic MI	RWMA, chronic remodeling changes	Negative	Subendocardial defect at rest matching thinned infarcted region, but can be normal in small infarcts after coronary revascularization	Thinned subendocardial or transmural LGE in a coronary distribution	Intracavitary thrombus may exist in areas of stagnant flow
Myocardial ischemia	Normal or RWMA	Negative	Reversible subendocardial perfusion defect in a coronary distribution	Normal	Subendocardial perfusion defect from significant coronary stenosis should persist beyond peak myocardial enhancement during first-pass transit of GBCA bolus Coronary MRA may show luminal stenosis
Idiopathic dilated CMP	Dilated, hypocontractile left/right ventricle	Negative	Normal	Midwall LGE, often in the septum	Mitral regurgitation secondary to dilated ventricle and mitral annulus may be present
HCM	Increased ventricular mass Asymmetric septal hypertrophy in some cases with or without LV outflow obstruction Spade-shaped LV chamber in apical HCM	Often abnormal	Abnormal in thickened myocardial segments may represent abnormal microcirculation	LGE at RV insertion into left ventricle or patchy midwall involvement in the hypertrophied segments	Outflow or midventricular obstruction by phase contrast imaging Systolic anterior motion of mitral leaflet ± mitral regurgitation May show reduced intramyocardial motion in hypertrophic regions Reversible perfusion defect may indicate abnormality of the coronary microcirculation.

**TABLE e17-3 Cardiac Magnetic Resonance Imaging (CMR) Findings That Differentiate Among Causes of Cardiomyopathy—cont'd**

STUDY INDICATION	CINE CARDIAC STRUCTURE/FUNCTION	MYOCARDIAL EDEMA	MYOCARDIAL PERFUSION	LGE IMAGING	ASSOCIATED CMR FINDINGS
ARVC	Right ventricle dilated/aneurysmal	Negative	Normal	RV often full thickness LGE matching location of the RV aneurysm ± LV focal LGE	Fatty infiltration of right and left ventricles focally may be seen by T1W FSE imaging and confirmed by fat suppression techniques “Nulling” of normal myocardium signal in the right and the left ventricles requires different inversion (TI) times
Acute myocarditis	RWMA and/or hypocontractile left ventricle	Usually transmural bright regions are seen, can be patchy or diffuse	Normal	Epicardial and midwall LGE involving inferolateral wall or septum	Pericardial involvement or effusion possible
Cardiac sarcoidosis	RWMA and/or hypocontractile left/right ventricle	Bright regions representing myocardial edema are variable	Normal	Multifocal intense LGE often involving the septum, inferolateral wall of the left ventricle, right atrium, and RV free wall	Mediastinal lymphadenopathy
Cardiac amyloidosis	Restrictive morphology, reduction of systolic thickening in LGE segments	Negative	Diffuse perfusion defect common	Diffuse circumferential (often subendocardial) LGE	Rapid gadolinium washout from LV blood pool after injection Difficulty in finding the right inversion time in “nulling” normal myocardium signal during LGE imaging Low endocardium/blood T1 ratio several minutes after contrast injection Thickened atrial walls with atrial LGE, loss of atrial contraction
Iron-overload CMP	Hypocontractile left ventricle with dark myocardium	Negative	Normal	Normal	Very low hepatic T2* value
LV noncompaction	Hypocontractile left ventricle with spongelike trabeculae, often in the lateral wall and the apex	Negative	Normal	Mid-wall or focal LGE	May see intracavitary thrombi
Apical ballooning syndrome	Circumferential ballooning and RWMA of all apical segments	Bright regions primarily involve the apical segments	Normal	Normal or only minimal subendocardial LGE	Patchy intermediate-intensity LGE without loss of wall thickness and T2W evidence of myocardial edema can be seen Reversal of abnormal findings after stressful events helps diagnosis
Endomyocardial disease	Dilated hypocontractile left and/or right ventricle	Negative	Normal	Diffuse subendocardial LGE of left or right ventricle ± thrombus	Cavitary thrombus can be seen on cine SSFP or LGE imaging with long inversion time; may be extensive to obliterate LV or RV apex
Fabry disease	Concentrically thickened left ventricle ± RWMA with wall thinning	Negative	Normal	Midwall LGE often in the inferolateral wall	Associated evidence of CAD possible

**TABLE e17-3** Cardiac Magnetic Resonance Imaging (CMR) Findings That Differentiate Among Causes of Cardiomyopathy—cont'd

STUDY INDICATION	CINE CARDIAC STRUCTURE/FUNCTION	MYOCARDIAL EDEMA	MYOCARDIAL PERFUSION	LGE IMAGING	ASSOCIATED CMR FINDINGS
Chagas disease	Often manifests as dilated and severe hypocontractile left ventricle during latent period of the disease	Negative in the latent period, positive if presented acutely	Normal	Resemble the pattern of healed viral myocarditis, with epicardial LGE involving the inferolateral wall common Apical aneurysmal changes have been described	—
Acute pericarditis	Often normal; pericardial effusion	Positive with myocardial involvement	Normal	Often normal but may see diffuse pericardial enhancement	Pericardial thickness often normal CMR better than echocardiography in assessing the extent and loculation of pericardial effusion
Chronic pericardial constriction	Small heart, large atria, and abnormal septal motion with respiratory variation during real-time cine imaging	Negative	Normal	Diffuse pericardial enhancement Myocardial involvement possible	Diffuse thickening (>3 mm) of pericardium seen by T1W FSE Constrictive tricuspid inflow pattern by phase contrast Bilateral pleural effusions Enlarged venae cava and tubular-shaped right ventricle
Cardiac mass	Proximity to an RWMA or a catheter, atrial fibrillation, recent endovascular procedure are associated with thrombus	Thrombus is dark on T2W imaging High SI may indicate edema with tumor mass	Thrombus is dark on first-pass perfusion imaging Cardiac tumors have variable degree of enhancement on first-pass perfusion	Mural thrombus may have an "etched" appearance on LGE imaging May see LGE within tumor mass from fibrosis	Most malignancies are metastatic rather than primary Recognize common normal structures: eustachian valve, Chiari network, crista sagittalis or terminalis, RV moderator band, and interatrial septal aneurysm Beware of "pseudotumors," e.g., coronary or aortic aneurysm, lipomatous hypertrophy of the interatrial septum, hiatal hernia, or catheters

RWMA = regional wall motion abnormality.

VIDEO 17-5

Myocardial rupture after acute inferior myocardial infarction in a 56-year-old man who presented with ventricular fibrillation. CMR demonstrates focal dyskinesis of the inferolateral wall and low signal intensity on late gadolinium enhancement imaging suggestive of intramyocardial hemorrhage (*arrow*). Pseudoaneurysm and a contained myocardial rupture was diagnosed by CMR and surgically confirmed.

is sensitive in predicting segmental contractile recovery. Even very thin myocardial regions without LGE have the potential for increase in thickness and recovery of function after revascularization.¹⁷ On the other hand, the high specificity from low-dose dobutamine cine imaging provides a physiologic assessment of the midmyocardial and subepicardial contractile reserve, particularly in segments with subendocardial MI involving less than 50% of the transmural extent. At our center, it appears that LGE imaging alone suffices for answering most questions raised in imaging for myocardial viability. However, low-dose dobutamine cine CMR can be complementary in assessing myocardial viability early after acute MI when tissue edema is prominent or when high test specificity is demanded to justify bypass surgery in patients at high preoperative risk.

Many earlier imaging-based viability studies were limited by retrospective design, lack of treatment assignment, and use of recovery of segmental function as an endpoint that provides little information about long-term patient outcomes. The Surgical Treatment of Ischemic Heart Failure (STICH) trial overcame the limitations of previous studies by prospectively assessing the role of viability imaging in decision-making toward cardiac bypass surgery or aggressive medical therapy in patients with CAD and LVEF below 35%.¹⁸ Although detection of myocardial viability was associated with patient survival, SPECT perfusion imaging or dobutamine echocardiography failed to identify patients who will derive the greatest survival benefit from addition of coronary artery bypass grafting (CABG) to aggressive medical therapy. One can postulate that because CMR can interrogate multiple targets of myocardial viability, it may provide a more precise viability assessment than SPECT or dobutamine echocardiography and may be more useful in guiding decision making in patients such as those studied in the STICH trial. Prospective studies of this issue are needed.

Detecting Acute Coronary Syndromes and Differentiating from Noncoronary Causes. A number of prospective single-center studies combined the diagnostic utility of cine wall motion imaging, myocardial perfusion, and LGE imaging using CMR in assessing acute chest pain syndromes. Collective evidence from these studies indicated that CMR has high sensitivity and specificity for detecting acute coronary syndromes and in risk-stratifying patients presenting with acute chest pain (Fig. 17-9). Adding T2-weighted imaging characterizing the acute area at risk to wall motion and LGE imaging can increase the specificity of diagnosing acute coronary syndrome in patients presenting with chest pain but with negative findings on ECG and serum troponin assays.¹⁹ Furthermore, T2-weighted imaging is unique in that the detection of the extent of the salvageable myocardium can be achieved for days after emergent restoration of coronary flow. Finally, CMR captures a range of abnormalities that are useful in differentiating acute coronary syndrome from noncoronary causes of chest pain.^{20,21}

Detecting and Quantifying Myocardial Ischemia. Based on current evidence from more than 30 single-center studies, 2 multicenter trials, and a randomized clinical study, summing to a clinical experience involving more than 7000 patients, a recent guideline

FIGURE 17-9 CMR assessment of acute coronary syndrome in a 63-year-old man 1 hour after his arrival at the emergency department. Initial cardiac enzyme levels were normal. **A**, A small area of T2 hyperintensity is evident in the inferolateral wall (myocardial edema), associated with subtle hypokinesis (**B**), a resting perfusion defect (**C**), and hyperenhancement on delayed imaging (De = MRI) (**D**), suggesting myocardial necrosis in the same area (arrows). Troponin level was elevated 7 hours after the imaging study. A subsequent invasive angiogram revealed triple-vessel disease with a 95% stenosis in the posterolateral branch. (From Cury RC, Shash K, Nagurney JT, et al: Cardiac magnetic resonance with T2-weighted imaging improves detection of patients with acute coronary syndrome in the emergency department. *Circulation* 118: 837, 2008.)

supports that pharmacologic stress CMR myocardial perfusion imaging (MPI) is a reasonable clinical tool for use in diagnosing CAD and risk assessment of patients with suspected myocardial ischemia.²² Combined interpretation of perfusion, LGE, and cine CMR data appear to yield the highest sensitivity and specificity for detection of coronary stenosis in patients presenting with acute chest pain. Compared with cardiac SPECT imaging (see Chapter 16), CMR MPI has several technical advantages: It is not limited by attenuation artifacts, it is free from ionizing radiation, and it has three- to four-fold higher spatial resolution than SPECT (Video 17-6). A stress CMR study that includes stress and rest perfusion imaging, cine cardiac function, and viability takes 35 to 45 minutes (compared with more than 2 hours for dual-isotope SPECT). CMR MPI also can characterize the dynamic range of myocardial blood flow without being limited by plateau effect of counts at high flow rates as seen in some nuclear tracers. In two separate reports from a multicenter, multivendor trial (MR-IMPACT), CMR MPI performed better than SPECT in detecting coronary stenosis (area under curve, 86% versus 67%), especially in the group of patients with multivessel stenosis (area under curve, 89% for CMR versus 70% for SPECT). In a recent randomized clinical study, Greenwood and associates reported superior sensitivity by CMR MPI when CMR and nuclear techniques were compared in a prospective trial using coronary angiography as the reference standard.²³ Fractional flow reserve assessment during angiography provides functional assessment of coronary stenosis and has been shown to improve patient management (see Chapters 49, 54, and 55). Watkins and co-workers demonstrated that CMR MPI has sensitivity of 91% and specificity of 94% in detecting functionally significant coronary stenosis defined by fractional flow reserve.²⁴ As summarized by the recent American Heart Association/American College of

**VIDEO 17-6**

Abnormal first-pass CMR perfusion from a severe left anterior descending arterial stenosis.

Cardiology Foundation guidelines for stable ischemic heart disease, CMR MPI is a clinical tool highly effective for patient risk assessment. As consistently shown in a number of single-center studies, patients with an intermediate pretest likelihood of CAD but negative CMR MPI have annualized cardiac event rates of less than 1%. Specifically, Steel and co-investigators reported complementary prognostic roles from stress perfusion and LGE imaging for unrecognized MI.²⁵ CMR MPI also has been shown to provide effective risk assessment in women.²⁶ Combining the wealth of diagnostic information from stress perfusion, function, and LGE imaging, CMR often provides clinicians with alternative diagnoses in patients suspected to have CAD. The recent EuroCMR registry of 11,040 patients reported that CMR identified a new or previously unsuspected diagnosis in 19.6% of patients and that the new diagnosis influenced management in 70% of patients.²⁷

Apart from qualitative reporting, CMR MPI can be analyzed quantitatively using the signal intensity versus time curves measured from myocardial segments. Accounting for arterial input function at different hemodynamic states and using a low dose of contrast injection are prerequisites in quantitative methods. Common *semiquantitative parameters* include signal upslope (rate of rise of the ascending curve), upslope integral (area under the upslope), and contrast enhancement ratio (ratio of peak to baseline signal intensity). *Fully quantitative analysis* of CMR perfusion yields absolute myocardial blood flow (in milliliters per minute per gram of tissue) using deconvolution methods and modeled compartmental analysis. Quantitative analyses have potential advantages including minimization of reader's bias and enhanced detection of abnormality in cases of balanced perfusion reduction or inadequate vasodilation.²⁸

Dobutamine stress CMR has been shown to have an excellent sensitivity (83% to 86%) and specificity (83% to 86%) in detecting CAD and is superior to dobutamine stress echocardiography (see Chapter 14). Such favorable results were consistent and maintained despite the presence of underlying resting wall motion abnormality. Multiple clinical studies have shown that dobutamine cine CMR provides strong prognostic value in risk assessment of patients.²⁹⁻³¹ The addition of stress myocardial perfusion and myocardial strain encoding during dobutamine stress can be a helpful adjunct to cine CMR in detecting myocardial ischemia.³² Accelerated real-time cine CMR imaging, which eliminates the need for patient breath-holding or ECG gating during dobutamine stress testing, has yielded encouraging preliminary results.³³ Treadmill exercise CMR is investigational currently but has been shown to be feasible in highly experienced centers.³⁴

Imaging of Atherosclerotic Plaques. Plaque structure and activity are key factors leading to plaque rupture. MRI of the carotid artery and the descending aorta remains the most comprehensive noninvasive method to characterize plaque structure and activity. The carotid bifurcation is relatively immobile, large, and superficial to the skin surface and shows the full spectrum of atherosclerotic lesion types. Most studies used a standardized protocol that consists of multiple contrast-weighted imaging sequences to identify carotid plaque fibrous cap, hemorrhage, calcifications, and loose matrix. Gadolinium-enhanced T1-weighted imaging helps to discriminate fibrous cap from necrotic or lipid core.³⁵ Carotid plaque neovascularization can be assessed by contrast-enhanced dynamic MRI by measuring the transfer constant between blood and the extracellular space and may provide prognostic information. Ultrasmall superparamagnetic particles of iron oxide (USPIO) may target macrophage activity based on histologic and electron microscopic analyses of atherosclerotic plaques, and such activity may be imaged using T2*-weighted MRI.³⁶ Similar to assessment of carotid plaque contents, CMR imaging of the thoracic aorta offers accurate quantitation of plaque size and insights into plaque composition, as well as complementary three-dimensional MRA over a large thoracic volume. Common to all imaging modalities, imaging of the coronary plaque is challenged by both cardiac and respiratory motion and the small vessel size, but future technological improvements with the use of exogenous targeted contrast agents, intravascular coils, and high-field CMR may offer promise. Use of a fibrin-binding contrast agent has been shown to enhance MRI detection of thrombus better than of an atherosclerotic plaque.

Cardiomyopathy Overall Approach

A summary of CMR protocols in assessing cardiomyopathies is presented in Table e17-2. CMR is a powerful tool in this regard owing to its multifaceted assessment of ventricular structure and myocardial

physiology, in matching arbitrary scan planes. CMR is routinely performed in experienced centers to complement echocardiography in assessing new cardiomyopathies. Table e17-3 summarizes the CMR features using rest and stress myocardial perfusion, regional function, LGE, and T2-weighted imaging in differentiating among myocardial viability, ischemia, infarction, and noncoronary causes of cardiomyopathy. In patients with valvular disease, volumetric cine CMR imaging can assess the loading impact onto the heart and the resultant ventricular compensation, which determine appropriateness of surgery. Tissue tagging may help to resolve any suspected regional wall motion abnormality at rest or stress or when myocardial adhesion from pericardial diseases becomes part of the issue of interest. Of importance, all of these major CMR techniques are not only accurate but also highly reproducible.³⁷ Although experience is still accumulating, CMR offers a unique opportunity to assess LV dyssynchrony, scar extent, and coronary venous anatomy in a single study. Both LV dyssynchrony and scar location are important predictors of echocardiographic response to cardiac resynchronization therapy (see Chapters 25 and 26).³⁸

Hypertrophic Cardiomyopathy

CMR cine imaging of LV structure and function and tissue characterization are useful in distinguishing physiological from pathologic forms of LV hypertrophy (LVH). Olivetto and colleagues reported substantial overlap in LV mass index values between patients with hypertrophic cardiomyopathy (HCM) (see Chapter 66) and normal control subjects from the Framingham Heart Study, in which at least 20% of patients with HCM have a normal LV mass index.³⁹ According to earlier reports, an end-diastolic wall thickness-to-cavity volume ratio less than 0.15 mm/mL/m² and a lack of abnormal LGE of the myocardium may differentiate physiologic from pathologic LVH. Limited echocardiographic windows lead to obliquity and errors in geometric measurements. It has been shown that echocardiography misses hypertrophic segments and underestimates the magnitude of hypertrophy in the basal anterolateral wall by as much as 33% when compared with CMR. In addition, 40% of apical aneurysms in patients with HCM are missed by echocardiography⁴⁰ (Fig. 17-10). All of these findings have important prognostic implications. In patients with HCM associated with severe septal hypertrophy and symptomatic dynamic LV outflow tract obstruction, CMR has an advantage over echocardiography in assessing the reduction of septal thickness from surgical myectomy or alcohol septal ablation (Fig. 17-11; Video 17-7). LV mass index varies widely with maximal LV wall thickness owing

FIGURE 17-10 Apical aneurysm in HCM. An apical aneurysm (arrow), which was not visualized on echocardiography, is seen on the CMR image. LA = left atrium; LV = left ventricle.

**VIDEO 17-7**

Mitral valve anomaly in hypertrophic cardiomyopathy. A 31-year-old woman with severe concentric left ventricular hypertrophy and severe outflow tract obstruction, in part a result of direct insertion of a papillary muscle into the anterior mitral leaflet (*arrow*). She underwent successful surgical septal myectomy with reconstruction and debulking of the anterior papillary muscle, and her obstruction was completely ameliorated. LA = left atrium; LV = left ventricle.

to heterogeneity of the HCM phenotype. Markedly elevated LV mass index ($>91 \text{ g/m}^2$ in men and $>69 \text{ g/m}^2$ in women) was sensitive (100% sensitivity), and maximal wall thickness greater than 30 mm was specific (91% specificity), for cardiac death.³⁹ Typical patterns of findings in HCM characterized by a multicomponent CMR study are listed in Table e17-3 and illustrated by a case example (Fig. 17-12). This approach may offer not only accurate HCM diagnosis but also further elucidation of myocardial pathophysiology. Petersen and associates found that blunted endocardial myocardial blood flow and myocardial fibrosis both were related to the degree of hypertrophy, raising the intriguing possibility that microvascular dysfunction plays an important role in the development of hypertrophy and myocardial fibrosis as a substrate to sudden cardiac death.⁴¹ In patients with HCM, LGE has been associated with ventricular arrhythmias and

progressive ventricular dilatation, and small series have suggested a relationship between presence of LGE, assessed visually, and adverse clinical events.^{42,43} By its concurrent assessment of altered physiology secondary to coronary microvascular dysfunction (Video 17-8), fibrosis, and hypertrophy, CMR will advance the understanding of both myocardial substrates and triggers relevant to selection of ICD therapy in patients with HCM.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic RV cardiomyopathy (ARVC) (see Chapter 65) is distinguished from other cardiomyopathies by (1) a predisposition toward ventricular arrhythmia that precedes overt morphological abnormalities and even histologic substrate and (2) diverse phenotypic manifestations despite success in isolating the causative desmosomal mutations. CMR offers advantages over echocardiography in its quantitative and volumetric assessment of RV function and its characterization of fibrofatty myocardial tissue. Recent evidence indicates that early and predominant LV disease exists in variant groups.⁴⁴ Enthusiasm for CMR was somewhat curbed by a lack of standardized imaging protocol in the past and inherent subjectivity in interpreting myocardial fat and wall motion abnormality of the thin-walled crescent-shaped right ventricle.⁴⁰ Recent efforts at standardization of CMR protocols have nonetheless affirmed the value of CMR as an integral component in the workup of ARVC. Currently, localized aneurysms, severe global dilation with systolic dysfunction, and severe segmental dilation of the right ventricle are considered major criteria as reported by the task force⁴⁵ (Fig. 17-13; Video 17-9). Fat-suppressed LGE imaging of RV fibrosis has shown a high correlation with endomyocardial biopsy findings and the inducibility of ventricular arrhythmias. Fat infiltration of the right ventricle as an isolated finding is of limited specificity for diagnosing ARVC. In patients suspected to have ARVC, CMR has a sensitivity of 96% and a specificity of 78% in detecting ARVC according to diagnostic criteria that includes genotype. This approach suggests that CMR potentially identifies patients with early disease not characterized by the task force guideline. Future studies are needed to determine the diagnostic and prognostic role of CMR relative to clinical evaluation, genetic analyses, and the new immunohistochemical analysis of plakoglobin signals. CMR will be crucial to gain new knowledge, along with the recent expansion of the genetic understanding of ARVC.⁴⁵

Myocarditis

CMR targets the three main pathophysiologic components of myocarditis (see Chapter 67): myocardial edema by T2-weighted imaging, regional hyperemia and capillary leak by early gadolinium enhancement ratio (EGE), and myocardial necrosis or fibrosis by LGE imaging (Fig. 17-14). Table e17-1 and a published expert consensus summarize the diagnostic criteria of these techniques for acute myocarditis.⁴⁶ From pooled data of the single-center studies, T2-weighted imaging, EGE, and LGE have individual sensitivities and specificities of 70% and 71%, 74% and 83%, and 59% and 86%, respectively. A combined approach using T2-weighted images and LGE provides high diagnostic accuracy for acute myocarditis⁴² (see Table e17-3). The subepicardium and midmyocardium of the inferolateral walls usually are involved, and parvovirus has been implicated, but septal involvement is associated with human herpesvirus 6, with potentially more serious sequelae.

FIGURE 17-11 Mitral valve anomaly in a 31-year-old woman with HCM and severe concentric left ventricular hypertrophy. Severe outflow tract obstruction was due in part to direct insertion of a papillary muscle into the anterior mitral leaflet (arrow). She underwent successful surgical septal myectomy with reconstruction and debulking of the anterior papillary muscle, and her obstruction was completely ameliorated. LA = left atrium; LV = left ventricle.

FIGURE 17-12 Tissue characterization in an asymptomatic 23-year-old woman with HCM and a strong family history of sudden cardiac death. Myocardial tagging (left panel) and cine imaging (middle panel) show septal wall thickness that is asymmetric to the lateral wall thickness. LGE imaging (right panel) demonstrates patchy areas of fibrosis in the area of maximal myocardial thickness, a finding that portends poor outcomes.

**VIDEO 17-8**

Microvascular dysfunction in a patient with hypertrophic cardiomyopathy. First-pass CMR myocardial perfusion imaging during vasodilating stress in a patient with hypertrophic cardiomyopathy. Note that there is diffuse hypoperfusion in all myocardial segments in this short-axis cut of the left ventricle. There is a transmural gradient of the severity of perfusion deficit (with endocardium being most severe). The diffuse and circumferential extent of this perfusion deficit are not consistent with epicardial coronary disease; rather, small vessel coronary disease is more likely. By x-ray angiography the patient has no epicardial coronary stenosis.

VIDEO 17-9

Cine CMR of a 50-year-old male presenting with recurrent ventricular tachycardia and syncope. Note the aneurysm of the basal RV free wall, which is consistent with a diagnosis of ARVC.

FIGURE 17-13 ARVC. The patient was a 24-year-old man who was referred for evaluation of palpitations and breathlessness. **A**, CMR image reveals a thickened and aneurysmal subtricuspid region (arrow) of the right ventricle (RV). **B**, Evidence of LGE (arrows) and **(C)** high signal intensity seen on FSE sequence are consistent with fibrotic changes and fatty infiltration, respectively, suggesting the diagnosis of ARVC.

FIGURE 17-14 Acute myocarditis. The patient was a 19-year-old college student who presented with marked diffuse ST-segment elevation and a serum troponin more than 100 times the upper limit of normal. Note the multiple areas of LGE (left panels and right lower panel) and diffuse T2 enhancement consistent with edema (right upper panel: green arrows highlighting regions of high signal in this SSFP cine image), strongly suggestive of the diagnosis of acute myocarditis.

Cardiac Sarcoidosis. The CMR techniques and corresponding findings in cardiac sarcoidosis (see Chapter 84) are listed in Tables e17-2 and e17-3. CMR may enhance disease detection through the successive histologic stages of disease: tissue edema, noncaseating granulomatous infiltration, and patchy myocardial fibrosis (Fig. 17-15). Patel and associates found that LGE imaging identified abnormalities consistent with cardiac sarcoidosis in 26% of patients compared with

12% of patients by the modified Japanese Ministry of Health guidelines. Among LGE-positive patients, a nine-fold increase was noted in the risk of death or major dysrhythmic events.⁴⁷ CMR also can be used to guide sampling during endomyocardial biopsy and increase tissue yield.

Cardiac Amyloidosis. The characteristic features of CMR techniques in cardiac amyloidosis (see Chapter 65) are summarized in Table e17-3 and Figure 17-16. A characteristic zebra stripe circumferential pattern of LGE involving the LV and even the RV subendocardium has been reported to have a sensitivity of 80% and a specificity of 94%.⁴⁸ Quantitatively, an inverse relationship has been documented between endocardial T1 and systemic and myocardial amyloid load. This transmural T1 gradient across the myocardium minutes after GBCA injection has been shown to be associated with cardiac death.⁴⁹

Idiopathic Dilated Cardiomyopathy

Major advantages of CMR in evaluating suspected idiopathic dilated cardiomyopathy (see Chapter 65) include ruling out ischemic cardiomyopathy, characterizing the pattern of LGE, which has diagnostic and prognostic implications, and monitoring of treatment response and disease progression. Subendocardial or transmural LGE consistent with infarction occurs in up to 13% of patients diagnosed with nonischemic dilated cardiomyopathy on the basis of nonobstructive coronary angiography.³⁷ On the other hand, current evidence indicates that in total absence of LGE, an ischemic cause of LV dysfunction is highly unlikely (Fig. 17-17). In a prospective randomized study, CMR using a combination of LGE and coronary MRA had a sensitivity of 100% and a specificity of 96% in diagnosing an ischemic cause of new-onset heart failure and provided substantial cost savings when used as a gatekeeper against invasive investigation.⁵⁰ Furthermore, in patients with cardiomyopathy but without angiographic coronary stenosis, 28% had patchy or

patchy or

FIGURE 17-15 Cardiac sarcoidosis. The patient was a 53-year-old man who presented with aborted sudden cardiac death. **A, B,** Note the intense subepicardial LGE in a noncoronary distribution (arrows), suggestive of cardiac sarcoidosis. The patient received a defibrillator for secondary prevention.

FIGURE 17-16 Cardiac amyloidosis. **Left,** There is thickening of the LV walls and enlarged left atrium (LA) without atrial contraction during end-diastole. **Right,** After contrast injection, diffuse endomyocardial enhancement of the LV and LA myocardium is evident. The dark-blood pool signal on LGE imaging is suggestive of amyloidosis-related sequestration of gadolinium from the blood pool, secondary to high systemic burden of amyloid.

FIGURE 17-17 Cardiomyopathy from cardiotoxic chemotherapy. The patient was a 72-year-old woman with a history of breast cancer and anthracycline treatment who was hospitalized for progressive dyspnea and volume overload. Normal first-pass perfusion and a lack of gadolinium enhancement were strongly suggestive of nonischemic cardiomyopathy due to cardiotoxic chemotherapy. Note the large transudative pericardial effusion (arrows).

linear midwall striae LGE, most often seen in the basal septum. Increased extent of LGE is associated with a lack of response to medical therapy⁵¹ and also with sudden death and inducible ventricular tachycardia, independent of LV size and function.³⁷

Iron Overload Cardiomyopathy

Iron overload cardiomyopathy (see [Chapter 65](#)) is either inherited or acquired. In patients with transfusion-dependent thalassemia major, cardiac death secondary to myocardial iron toxicity occurs in 50% of patients. Serum ferritin and hepatic iron levels do not reflect cardiac iron overload because of a different transport mechanism from that in the heart,

and chelation therapy readily removes iron from the liver. Global systolic LV function usually is preserved, especially in anemic thalassemic patients, until severe cardiac toxicity has developed, and thus provides little if any guidance to chelation therapy. The CMR T2* technique for quantifying myocardial iron is summarized in [Table e17-1](#). CMR T2* quantitation has been shown to improve delivery of iron chelation therapy and as a consequence led to substantial reduction of mortality in patients with thalassemia major.⁵² In patients with reduced ventricular function, a T2* less than 20 milliseconds is consistent with iron overload (see [Fig. 17-5](#)). Patients with a myocardial T2* less than 10 milliseconds are at the highest risk for developing heart failure within 1 year.

Other Cardiomyopathies

Chagas disease is a myocarditis caused by infection from the protozoan *Trypanosoma cruzi* endemic in Central and South American countries. Although most patients experience a self-limited course, about 30% will have persistent parasitemia and latent infection that manifest years later as a dilated cardiomyopathy often associated with ventricular arrhythmias. CMR is useful in diagnosing (see [Table e17-3](#)) and monitoring patients infected with this disease during the latent period. *LV noncompaction* is a cardiomyopathy characterized by failure of compaction of the trabecular layer ([Fig. 17-18](#); see also [Table e17-3](#)), with a familial pattern reported in approximately 40% of patients. A diastolic noncompacted-to-compacted thickness ratio greater than 2:3 measured in a long axis was 86% sensitive and 99% specific for diagnosing this condition. *Transient LV apical ballooning syndrome* (or takotsubo cardiomyopathy) is characterized by a

FIGURE 17-18 Left ventricular noncompaction. **A, B**, Note the heavy trabeculations in the left ventricle (LV) and right ventricle (RV) (asterisks), with a ratio of trabeculated myocardium to nontrabeculated myocardium of 5:1. LA = left atrium; RA = right atrium.

FIGURE 17-19 Takotsubo cardiomyopathy. The patient was a 58-year-old woman who was referred for CMR after a coronary angiogram revealed no obstructive disease despite the presence of ST-segment elevations on ECG and positive biomarker assays. A diagnosis of takotsubo cardiomyopathy was made on the basis of the CMR image, which shows LV apical akinesis and ballooning (arrow). LV = left ventricle.

FIGURE 17-20 Hyper eosinophilic syndrome. The diffuse subendocardial LGE (arrows), in a noncoronary distribution, is consistent with endomyocardial fibrosis. LV = left ventricle.

transient contractile dysfunction of the apex, due to elevated catecholamines from severe emotional or physical stress (**Fig. 17-19**; Video 17-10). CMR can be useful in differentiating apical ballooning syndrome from an acute coronary event (see **Table e17-3**). *Endomyocardial disease* is a restrictive cardiomyopathy that consists of two variants: endomyocardial fibrosis and Löffler endocarditis; both were considered the result of direct toxic effects of eosinophils on the myocardium. Hypereosinophilia regardless of cause has been suggested to lead to cardiomyopathy in three stages: necrosis, thrombosis, and fibrosis. Hypereosinophilia is the hallmark of Löffler endocarditis, whereas it is variably present in endomyocardial fibrosis, which has characteristic features on CMR imaging (**Fig. 17-20**; see also **Table e17-3**).

Diastolic Dysfunction

As with other modalities, CMR quantitation of diastolic filling rates and time to peak filling are influenced by cardiac chronotropic state and left atrial pressure. Phase contrast velocity imaging has been shown to accurately measure mitral inflow and pulmonary venous velocities (validating against Doppler echocardiography findings) over a practical scan time of several minutes. With the advantage of unrestricted scan planes, early mitral inflow velocity (E) normalized to in vivo mitral septal tissue velocity (Ea) measured using phase contrast CMR can estimate

mean pulmonary capillary wedge pressure. CMR-specific tissue grid tagging can determine the rotational and translational motion of the LV myocardium by characterizing the clockwise and anticlockwise rotation at the base and the apex, respectively, during systole. With adequate temporal resolution (less than 35 milliseconds), quantitation of grid distortion permits direct assessment of diastolic intramyocardial deformation measured in strain and strain rate.

Pericardial Disease

A typical CMR assessment of pericardial disease (see **Chapter 71**) includes cine SSFP imaging, T1- and T2-weighted double-inversion black-blood FSE (half-Fourier acquisition single-shot turbo spin-echo, HASTE) sequences, and LGE imaging of the whole heart to assess for pericardial changes (**Fig. 17-21**). Real-time cine SSFP and phase contrast flow across the tricuspid valve often are added to the examination, to enhance the detection of cardiac constriction (**Fig. 17-22**; Video 17-11). First-pass perfusion and pre- and postcontrast T1-weighted techniques also may be necessary to determine vascularity of a pericardial mass (e.g., to differentiate tumor versus thrombus). Cine myocardial-tagged (using dark lines or grids) imaging may be useful to identify any regional concordance due to perimyocardial adhesions. Single-shot and real-time methods increase the diagnostic yield of the study in patients with irregular heart rhythms. A description of the CMR protocol is summarized in **Table e17-2**. With T1-weighted FSE imaging, a thickness of up to 3 mm is accepted as

**VIDEO 17-10**

Takotsubo cardiomyopathy. A 58-year-old woman was referred to CMR after coronary angiogram revealed no obstructive disease despite the presence of ST-elevations on ECG and positive biomarkers. A diagnosis of Takotsubo cardiomyopathy was made on the basis of the CMR, which shows left ventricular (LV) apical akinesis and ballooning (*arrow*).

VIDEO 17-11

Chronic constrictive pericarditis with pericardial Adhesions post radiation. A 62-year-old woman with a history of breast cancer and radiation therapy presented with fatigue and breathlessness. Note the presence of adhesions (*red arrows*) in the pericardial space. A diagnosis of pericardial constriction was made by CMR.

normal. Pericardial sinuses often are mistaken for pathologic processes or lesions. The transverse sinus (lies dorsal to the ascending aorta) and the superior pericardial recess (a curvilinear space to the right of the ascending aorta) may be mistaken for an aortic dissection or a mediastinal mass. The oblique sinus, behind the left atrium, may be misinterpreted as an esophageal lesion or bronchogenic cysts. Enhancement of the thickened pericardium after the administration of GBCA suggests active inflammation or pericardial fibrosis (Fig. 17-23). CMR is the current test of choice for differentiating constrictive pericarditis from restrictive cardiomyopathy, not only by assessing pericardial thickness but also by detecting signs of constrictive physiology. Computed tomography can demonstrate pericardial calcifications (see Chapter 18) but is inferior to CMR in its limited hemodynamic data and tissue characterization.

Pericardial cysts usually have thin smooth walls without internal septa. Their homogeneous transudative contents appear dark on T1-weighted images and bright on T2-weighted images, with no enhancement from GBCA. Proteinaceous cysts appear very bright on T1-weighted images. Pericardial metastases are far more common (from lung and breast cancers and lymphomas) than primary pericardial tumors. Malignant invasion of the pericardium often shows focal

FIGURE 17-21 Chronic constrictive pericarditis with pericardial adhesions. The patient was a 62-year-old woman with a history of breast cancer and previous radiation therapy who presented with fatigue and breathlessness. Note the presence of adhesions (red arrows) in the pericardial space. A diagnosis of pericardial constriction was made by CMR.

FIGURE 17-22 CMR imaging of constrictive physiology from pericardial disease. The patient was a 57-year-old woman with lupus who presented with pleuritic chest pain and lower extremity edema. **A**, A mildly thickened pericardium (black, between the arrows) is evident on the dark-blood CMR image. Auscultation demonstrated a classic multicomponent friction rub. **B**, Real-time velocity-encoded cine image acquired during free breathing across the atrioventricular valves shows discordant right-sided (green) versus left-sided (red) filling of the heart. These findings are diagnostic for constrictive physiology, which may be present even without significant pericardial thickening. (Courtesy Subha Raman, MD, Ohio State University Medical Center, Columbus, Ohio.)

obliteration of the pericardial line with a pericardial effusion. Most neoplasms appear dark or gray on noncontrast T1-weighted images, except metastatic melanoma, owing to its paramagnetic metals bound by melanin (Fig. 17-24).

Partial absence of the pericardium usually is left-sided and can be associated with other congenital defects. Absence of pericardium is suspected when lung tissue is seen interposed between the aorta and the pulmonary artery or between the heart and the diaphragm.

Adult Congenital Heart Diseases

CMR can provide key additive data beyond information obtained with other imaging methods in assessment of congenital heart disease based on the following factors: no need for ionizing radiation, three-dimensional tomographic imaging of thoracic structures, and correlation of complex anatomy with blood flow and physiology. Discussed next is the application of CMR in common adult congenital heart diseases (see Chapter 62).

Atrial and Ventricular Septal Defects

CMR can provide a noninvasive alternative to transesophageal echocardiography and even to diagnostic catheterization in assessing patients presenting with right-sided volume overload from a suspected left-to-right shunt. A CMR study can detect the presence of an atrial septal defect (ASD), assess suitability for transcatheter ASD closure (see Chapter 56), quantify right heart size and function by cine SSFP, determine pulmonary-to-systemic shunt ratio (Qp/Qs) using velocity-encoded phase contrast, and identify any coexisting anomalous pulmonary venous return using three-dimensional contrast-enhanced MRA. Phase contrast imaging positioned in a plane parallel to the atrial septum and set at a low velocity range (100 cm/sec) can visualize the ASD en face with good correlation with defect size measured invasively. Phase contrast imaging of the tricuspid regurgitation can estimate the pulmonary arterial systolic pressure. Because most closure devices are MRI-compatible, CMR can be used to assess for residual shunt and proper device deployment. Patients with a ventricular septal defect (VSD) can be assessed using similar CMR techniques. In addition, LGE imaging may help to determine if a VSD developed as a complication from MI.

Anomalous Pulmonary Venous Connection

Using a large field of view, three-dimensional MRA can capture abnormal intrathoracic structures and vascular dynamics in anomalous pulmonary venous return. Near-isotropic in-plane resolution can be achieved, allowing reformatting in any plane to detect anomalous venous structures as small as 1 mm (Fig. 17-25). The magnitude of any left-to-right shunt can be assessed either by direct blood flow measurements in the anomalous pulmonary vein or by determination of the Qp/Qs ratio described previously, which is in general more accurate than invasive oximetry measurements, owing to the errors from mixed venous return in the right atrium.

Coarctation of the Aorta

With coarctation of the aorta (see Chapter 57), gadolinium-enhanced three-dimensional MRA is sufficient in defining the site of aortic narrowing in most cases. Cine SSFP using a long-axis “candy cane” view can further delineate the aortic anatomy, the degree of obstruction, aortic valvular dysfunction (since bicuspid aortic valve often coexists in patients with coarctation of the aorta), and the effects of hypertension. Cine SSFP is the gold standard for assessing LV size, LV function,

FIGURE 17-23 Pericardial inflammation by CMR. The patient was a 43-year-old woman with systemic lupus and a history of pericarditis in whom CMR imaging showed pericardial constriction. **A**, The pericardium is thickened and enhanced on T2-weighted images (arrow), as well as on LGE sequences (asterisks) in multiple imaging planes (**B-D**). AO = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle.

FIGURE 17-24 Metastasis to the myocardium. The patient was a 71-year-old man with a history of melanoma who was referred for evaluation of a pericardial mass (arrow). Both bright-blood (**A**) and black-blood (**B**) sequences are suggestive of metastatic melanoma invading the myocardium. LV = left ventricle; RV = right ventricle.

FIGURE 17-25 Scimitar syndrome with anomalous venous return from the right lung is demonstrated on this surface-rendered three-dimensional magnetic resonance pulmonary venous angiogram. IVC = inferior vena cava; SV = "scimitar vein."

and myocardial mass. Black-blood FSE is useful to evaluate the entire aorta particularly because it is less affected by metallic artifacts from implanted endovascular stents than gradient-echo techniques. Phase contrast imaging can characterize the descending-to-ascending aorta flow ratio and estimate the pressure gradient across the coarctation as well as collateral formation.

Conotruncal Anomalies

Tetralogy of Fallot (TOF) is an increasingly common diagnostic reason for referral for CMR investigation. In patients undergoing evaluation for planned surgical repair, key elements provided by CMR include depiction of all sources of pulmonary blood flow (including pulmonary arterial, aortopulmonary collateral, and ductus-arterial sources) in the presence of RV outflow obstruction, quantitation of the severity of infundibular or pulmonary stenosis, assessment of RV function, and ruling out a coexisting anomalous coronary artery. In patients who have undergone surgery for TOF, CMR provides relevant assessment for any RV outflow aneurysm, pulmonary regurgitation fraction (patients who underwent patching of the pulmonary valve with postoperative pulmonary regurgitation), biventricular size and function, and any residual shunt.⁵³ LGE imaging has been proposed for detection of myocardial fibrosis, which is associated with ventricular dysfunction, exercise intolerance, and arrhythmias (Fig. 17-26).

The principal physiologic abnormality in *D-loop transposition of the great arteries* (TGA) (D-loop being the commonest type of TGA) is profound hypoxemia secondary to ventriculoarterial discordant connection whereby systemic venous blood goes to the aortic and oxygenated pulmonary venous blood returns to the lung. Survival is dependent on systemic-pulmonary circulatory mixing via a ductus arteriosus, an ASD, or a VSD. An arterial switch operation is now the most common corrective surgery, but many adult patients have undergone an atrial switch procedure. CMR is useful in monitoring these patients after surgical correction by serially assessing ventricular size and function, flow across the postoperative LV and RV outflow tracts, and aortopulmonary collaterals.

Valvular Heart Disease

With capability to assess cardiac structure and function, valvular and great vessel flow hemodynamics, and three-dimensional angiography, CMR provides complementary information to that obtained by echocardiographic evaluation of valvular heart disease (see Chapter 63). Compared with echocardiography, CMR is thus more sensitive in detecting three-dimensional change in ventricular size, function, and myocardial mass. For aortic stenosis, CMR can visualize and achieve direct planimetry of the aortic valve orifice at high spatial resolution (Fig. 17-27). Aortic valve area on CMR correlates well with that seen by transesophageal echocardiography (see Chapter 14), although the reliability of CMR decreases when the aortic valve is

heavily calcified. Because phase contrast CMR imaging has lower temporal resolution than echocardiography, it may underestimate the peak velocity of blood flow across a stenotic aortic valve compared with Doppler. CMR quantification of aortic regurgitation has high accuracy (see Fig. 63-14) and complements LV volumes in characterizing the progression of the regurgitant disease toward clinical need for surgery.⁵⁴ The ability of CMR techniques to provide high-quality imaging of structure and physiology of the great vessels complements the assessment of valvular dysfunction (Fig. 17-28). A novel application of CMR in identifying vortical blood flow in the pulmonary artery has been shown to estimate mean pulmonary arterial pressures and differentiate patients with pulmonary hypertension.⁵⁵ Three-dimensional volumetric phase contrast imaging has been developed that allows visualization of vascular “vector” flow for assessment of vascular wall shear stress or cavitory flow dynamics.⁵⁶ This three-dimensional vector flow may allow elucidation of the relation between valvular dysfunction and the progression of the resultant ventricular dysfunction (Fig. 17-29; Videos 17-12 and 17-13).

Cardiac Thrombus and Mass

Considerations in the differential diagnosis of an intracardiac mass include a thrombus, tumor, or vegetation. LGE imaging can detect

FIGURE 17-26 The patient was a 28-year-old man with repaired tetralogy of Fallot. The patch closing the VSD is seen on this LGE image in the three-chamber orientation (arrow). The patch is densely fibrotic, as indicated by its high signal intensity. The flattening of the interventricular septum is secondary to volume overload of the right ventricle from severe residual pulmonary regurgitation. Ao = aorta; LV = left ventricle; RV = right ventricle. (Courtesy François-Pierre Mongeon, MD, SM, FRCPC, Montreal Heart Institute, Université de Montréal, Montreal, Quebec, Canada.)

FIGURE 17-28 Acute aortitis. Note the thickened aortic wall (A, B) matched by intense LGE (C), consistent with inflammation of the aorta. (Courtesy Patricia Bandettini, MD, National Institutes of Health, Bethesda, Md.)

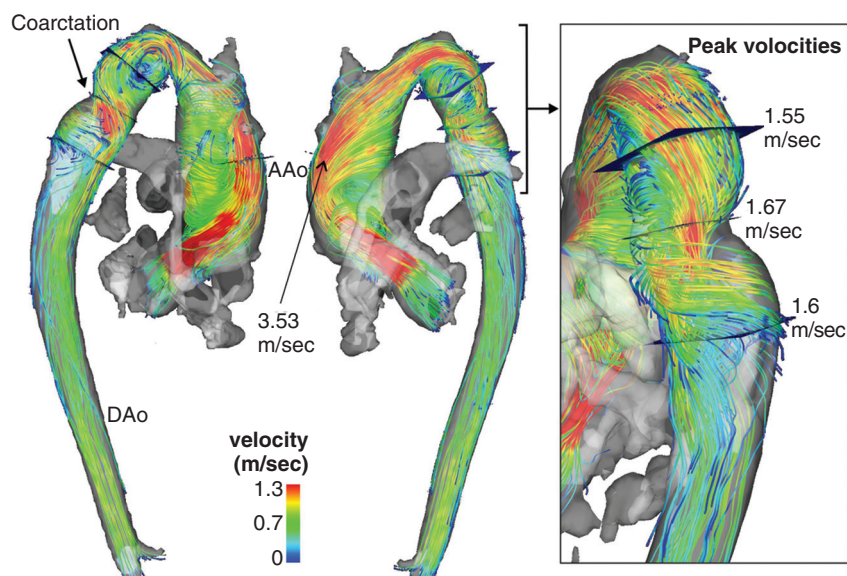

FIGURE 17-29 Three-dimensional streamline visualization of thoracic aorta systolic blood flow as assessed by four-dimensional flow MRI. The patient was an asymptomatic 33-year-old man with a bicuspid aortic valve (BAV) with fusion of the right and left coronary leaflets and aortic coarctation at the proximal descending aorta (DAo). Three-dimensional flow visualization and peak velocity quantification demonstrate a posteriorly directed, high-velocity flow jet in the ascending aorta (AAo) with associated right-handed helix formation. Complex aortic geometry near the coarctation results in vortex formation proximal to the coarctation, a right-handed helix distal to the coarctation, and flow acceleration through the aortic narrowing. This case illustrates the potential for four-dimensional flow MRI to capture the impact of localized pathologic processes on complex changes in aortic hemodynamics affecting the entire thoracic aorta. In addition, the complete volumetric coverage identifies the optimal location for retrospective quantification of clinically relevant parameters such as peak jet flow velocities distal to the BAV and within the coarctation. (Courtesy Michael Markl, PhD, and Bradley D. Allen, MD, Departments of Radiology and Biomedical Engineering, Northwestern University, Chicago.)

thrombus at a higher sensitivity than echocardiography by depicting high contrast between the dark thrombus and its adjacent structures and by imaging in three-dimensional mode. Mural thrombus does not enhance on first-pass perfusion and often has a characteristic “etched” appearance on LGE imaging, thus providing higher diagnostic specificity than that possible with anatomic information alone (Fig. 17-30). Multiple pulse sequences can be used to detect vascularity of tumor after contrast injection, allowing differentiation from thrombus (Fig. 17-31; Video 17-14). Setting inversion time of LGE imaging to 600 milliseconds, however, allows recovery of signal in tissues except thrombus, which stays dark, thereby providing a sensitive and specific means of detection of mural thrombus.

Common benign cardiac tumors include atrial myxoma, rhabdomyoma, fibroma, and endocardial fibroelastoma. Atrial myxomas often are seen as a round or multilobar mass in the left atrium (75%),

right atrium (20%), or ventricles or mixed chambers (5%). They typically show inhomogeneous brightness in the center on cine SSFP imaging, reflecting their gelatinous content, and may have a pedunculated attachment to the fossa ovalis. Metastatic cardiac malignancy is much more common than primary cardiac malignancy; malignant lesions include cardiac involvement from direct invasion (lung and breast cancers), lymphatic spread (lymphomas and melanomas); and hematogenous spread (renal cell carcinoma). Primary cardiac malignancies occur more often in children or young adults. These lesions include angiosarcoma, fibrosarcoma, rhabdomyosarcoma, and liposarcoma. CMR in a multicenter trial correctly diagnosed 97% of these cases, although further investigation to resolve a differential diagnosis was necessary in 42%.⁵⁷

NOVEL CARDIAC MAGNETIC RESONANCE IMAGING TECHNIQUES

T1 and T2 Mapping

T1 mapping estimates in quantitative terms the expansion of the extracellular space in the myocardium where GBCAs distribute. This method has demonstrated good correlation with collagen content of the interstitial space.⁵⁸ Figure 17-32 illustrates the T1 mapping method we use at our institution. Important differences bring about the need to use T1 mapping, rather than using T1-weighted imaging. Diffuse myocardial fibrosis, in contrast with acute or chronic MI tends to affect the entire myocardium, thereby removing the possibility of use of some reference region (e.g., a myocardial region remote from an infarct) to highlight fibrosis.

Using both pre- and postcontrast T1 measurements, one can determine the change of $R1$ ($= 1/T1$) between pre- and postcontrast states in myocardium relative to the change of $R1$ in blood. This ratio estimates the tissue volume fraction filled by extracellular GBCA. Compared with T1-weighted imaging techniques such as LGE imaging, important reasons for using T1 mapping include sensitive quantitation of subtle changes in extracellular volume as a result of fibrosis or infiltration and correction for spatial variations of myocardial signal intensity relative to the distance from the surface coil. T1 mapping techniques in early clinical studies have characterized significant changes in the myocardium not visible by LGE imaging.^{59,60}

Myocardial T2 mapping has been introduced to detect myocardial edema. T2 mapping, which involves acquisition of a series of images with different T2-weighting provides a quantitative measurement of

**VIDEO 17-14**

Cine imaging of a patient with a large mass attached to the mitral valve before (**left**) and after (**right**) contrast was injected. This video illustrates characterization of tissue vascularity of the cardiac mass. The mass demonstrated substantial signal enhancement after contrast injection, indicative of its high vascularity. This mass lesion was a large spindle-cell carcinoma of the heart primarily affecting the mitral valve.

FIGURE 17-30 CMR detection of intracardiac thrombus. The patient was a 60-year-old man with apical akinesis after an anterior wall infarction who was referred for CMR imaging after a transient ischemic attack event. LGE sequence with a long inversion time demonstrates a large apical thrombus (arrow). LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

FIGURE 17-31 Tissue characterization of cardiac mass. The patient had a large spindle cell carcinoma of the heart primarily affecting the mitral valve (arrow). The mass demonstrated substantial signal enhancement after contrast injection, indicative of its high degree of vascularity. LA = left atrium; LV = left ventricle.

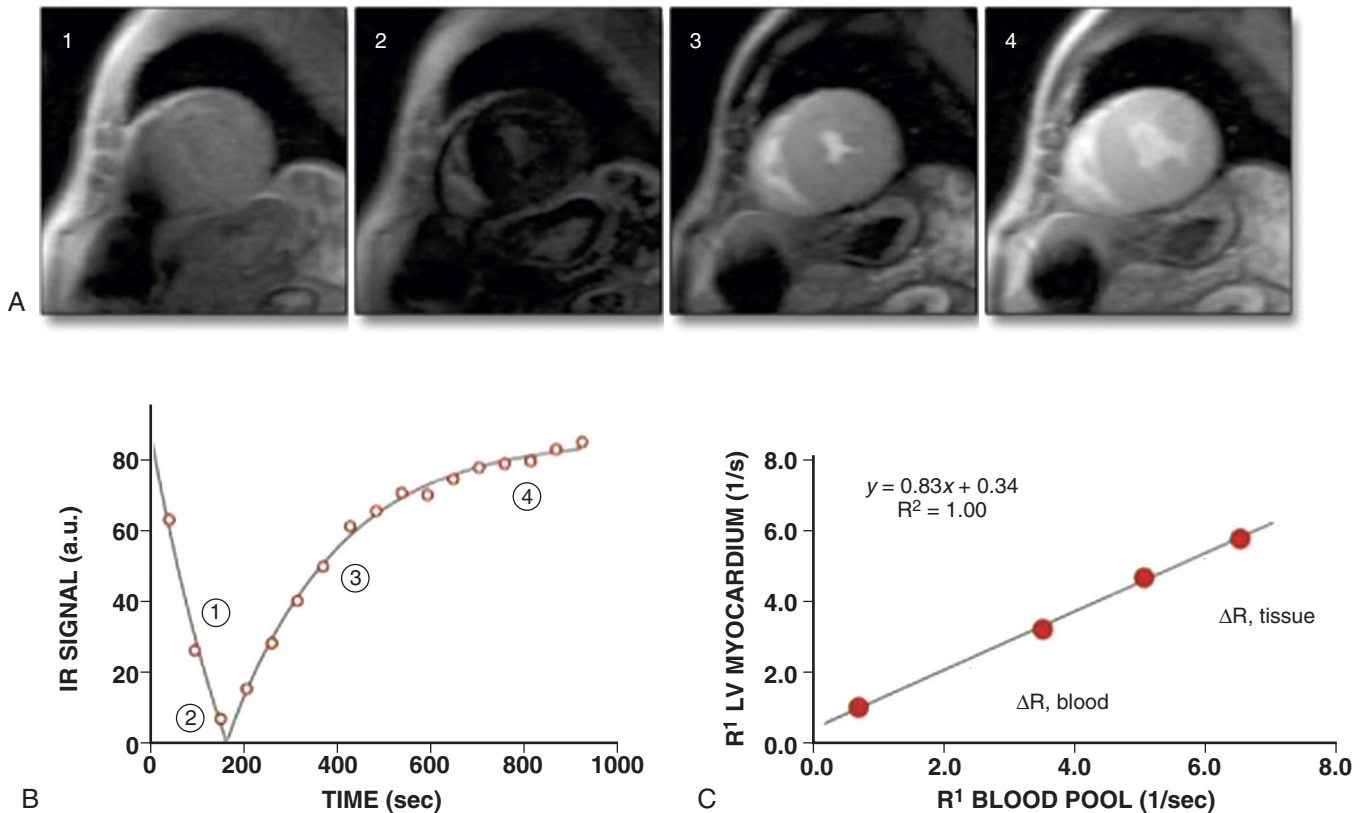

FIGURE 17-32 T1 mapping of the myocardium. T1 mapping involves a series of images after a magnetization inversion pulse, as illustrated by images 1 through 4 in this example (panel A). One can then derive the rate constant (T_1) for the recovery of the signal after the inversion by putting a region of interest onto all images acquired after the inversion pulse (panel B). By deriving the ratio of change in rate constants in the myocardium versus blood pool (i.e., slope of the straight line of panel C) and correcting for the patient's hematocrit, one can derive an estimate of the extracellular volume of the myocardium. R_1 and R_2 are reciprocals of T_1 and T_2 , respectively. (Courtesy Michael Jerosch-Herold, PhD, Brigham and Women's Hospital, Boston.)

regional fraction of free water in the myocardium. Compared with T2-weighted imaging, T2 mapping renders the detection of edema more reliable, corrects for the coil sensitivity variation of signal intensity, and is less prone to artifacts from either motion or arrhythmia. Pilot clinical studies have reported usefulness of T2 mapping in heart transplant rejection, inflammatory cardiomyopathies, and acute ischemia.⁶¹⁻⁶³

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) provides information regarding cellular metabolism. Free energy in adenosine triphosphate (ATP) is produced and stored primarily in mitochondria and carried to sites of energy consumption (e.g., myofibrils or ion channels) as phosphocreatine (PCr) through diffusion. Phosphorus-31 MRS assesses energy metabolism and hence the integrity of cellular

function by quantifying the ratio of PCr and ATP. MRS currently is limited by the low signal-to-noise ratio owing to low concentration of the high-energy phosphate molecules, resulting in a limited sensitivity for detection of viable myocardium beyond the anterior LV. However, proton (^1H) MRS has up to 20-fold improved sensitivity over that for ^{31}P MRS and thus can quantify both phosphorylated and unphosphorylated creatine in any part of the left ventricle. Using ^1H MRS, lipid overstorage was observed in human myocytes in diabetics in the absence of systolic dysfunction, which may have implications for the development of diabetic cardiomyopathy.⁶⁴

Cardiac Magnetic Resonance Imaging at 3T

Increasing the field strength offers the promise of higher signal-to-noise ratio, which leads to higher image quality, imaging speed, and spatial resolution. Compared with 1.5T techniques, pulse sequences such as myocardial perfusion imaging and LGE imaging are readily improved from the higher signal-to-noise ratio at 3T. At 3T, the benefit of parallel imaging can be used in more applications, thereby enhancing sequence efficiency with an acceptable loss of signal-to-noise ratio. Because resonance frequencies of spins in water and fat are more widely separated at 3T, fat suppression imaging also can be more precise. Both T2 and T2* are shorter, so structures of low signal intensity such as blood clots are more easily seen as dark structures in 3T. The elevated signal-to-noise ratio has facilitated the advance of novel applications such as blood oxygen level deoxygenation (BOLD) perfusion and MRS. Several technical problems, however, are recognized for CMR imaging at 3T, including higher chance of patient tissue heating, chemical shift and off-resonance artifacts with use of SSFP imaging, and challenges in cardiac gating.

Molecular Cardiac Magnetic Resonance Imaging

Molecular CMR imaging can theoretically provide dramatic improvement in sensitivity and specificity of disease detection by characterizing cellular process and also allow preclinical disease detection. Use of gadolinium chelates combined with a fibrin-specific peptide ligand has been demonstrated to detect thrombi in the left atrium and coronary stents under experimental conditions. Other examples are the use of nanoparticles to target the adhesion molecule $\alpha_v\beta_3$ -integrin as a marker of angiogenesis in atherosclerosis, and of USPIO particles to detect macrophages in inflamed carotid plaques, and tracking of intramyocardial transplanted mesenchymal stem cells in experimental infarction.⁶⁵

Cardiac Magnetic Resonance Imaging for Testing Novel Cardiovascular Therapies

By providing a platform to quantify multiple physiologic parameters, CMR has played a role in testing of novel therapies. LGE imaging has been used in numerous clinical trials of such therapies for reducing infarct size in acute MI.^{66,67} In experimental models, CMR has been used for in vivo tracking of stem cells and their survival.⁶⁸ In clinical studies, quantitative assessment of LV function and LGE by CMR techniques showed that autologous cardiac stem cells infused during CABG resulted in improvement in LVEF and reduction in infarct size.⁶⁹ In patients undergoing imaging assessment for transcatheter aortic valve

implantation (see Chapters 56 and 63), aortic annulus measurement by CMR was better than that by echocardiography in predicting the presence and severity of postprocedural aortic regurgitation.⁷⁰

FUTURE PERSPECTIVES

Technological advances in CMR in the next years are likely to focus on improving the study throughput, protocol consistency, and patient tolerability. Faster data collection achieved by combining efficient parallel imaging algorithms and improved surface coil elements may reduce or eliminate the need for patient breath-holding and reduce CMR scan time. With more efficient data collection methods, time-resolved techniques such as cine imaging may be replaced by real-time imaging. Using three-dimensional pulse sequences or performing CMR imaging at 3T can offset the reduction in signal-to-noise ratio secondary to data undersampling by parallel imaging. It is therefore conceivable that these combinations of methods will replace the current two-dimensional standard methods. Semi-automated cardiac localization and scanning algorithms will be developed to reduce the time required in training physicians and technologists.

New contrast agents hold promise in improving the assessment of myocardial or vascular physiology. For example, a contrast agent with perfusion-dependent reversible binding to myocardial collagen has the potential of substantially improving the quality of CMR myocardial perfusion imaging and enabling the option of performing exercise stress before CMR imaging.⁷¹ Blood-pool contrast agents may improve delineation of coronary stenosis by whole-heart coronary MRA and assessment of myocardial perfusion.⁷²

Although further development is needed in interventional instrumentation and MRI hardware, CMR-guided interventions, especially for electrophysiologic applications, hold promise in improving ablative procedures (Fig. 17-33).

The role of CMR is likely to expand in both clinical decision making and research applications. The former application is supported by the ability of CMR to combine information on cardiac structure and physiology, a growing understanding of the CMR technology and acceptance in the clinical cardiology community, and an increasing awareness of the risk of medical radiation exposure. The expanded research applications are evidenced by the high reproducibility of quantitative CMR results in reducing study sample sizes and costs demanded for testing novel therapies in clinical trials. Ongoing studies that assess for any cost-benefit improvement by CMR will further define the future directions of this modality as a diagnostic tool.

FIGURE 17-33 CMR imaging in preparation for RF ablation of atrial fibrillation. **Left**, A patient with atrial fibrillation was referred for CMR-guided RF ablation. **Right**, Note the presence of scar in the atria on LGE imaging (arrows), corresponding to the areas of ablation.

APPROPRIATE USE CRITERIA

Cardiovascular Magnetic Resonance Imaging

Raymond Y. Kwong

The explosive growth in cardiovascular imaging has sometimes outpaced the evidence on which use of new technologies should be based. In an effort to guide rational use of these technologies, eight scientific organizations—the American College of Cardiology Foundation, American College of Radiology, Society of Cardiovascular Computed Tomography, Society for Cardiovascular Magnetic Resonance, American Society of Nuclear Cardiology, North American Society for Cardiac Imaging, Society for Cardiovascular Angiography

and Interventions, and Society of Interventional Radiology—have embarked on a process to determine the appropriateness of selected indications for cardiovascular imaging procedures.

Panelists rated 33 indications for cardiac magnetic resonance (CMR) as appropriate (7 to 9 points), uncertain (4 to 6 points), and inappropriate (1 to 3 points), based on the following definition of appropriateness:¹

An appropriate imaging study is one in which the value of the expected incremental information, combined with clinical judgment, exceeds the expected negative consequences by a sufficiently wide margin for a specific indication, so that the procedure generally is considered acceptable care and a reasonable approach for the indication. (Negative consequences include the risks associated with the procedure [e.g., radiation or contrast exposure] and the downstream impact of poor test performance such as delay in diagnosis [false negatives] or inappropriate diagnosis [false positives].)

Of the 33 CMR indications, 20 were deemed appropriate, 4 were uncertain, and 9 were rated as inappropriate (Table 17G-1).

TABLE 17G-1 Joint Professional Society* Evaluation of Appropriate Indications for Cardiac Magnetic Resonance Imaging

INDICATION	APPROPRIATENESS (MEDIAN SCORE)
Detection of CAD: symptomatic	
<i>Evaluation of chest pain syndrome (use of vasodilator perfusion CMR or dobutamine stress function CMR)</i>	
Intermediate pretest probability of CAD ECG uninterpretable or unable to exercise	A (8)
High pretest probability of CAD	A (7)
Intermediate pretest probability of CAD ECG interpretable and able to exercise	U (4)
Low pretest probability of CAD ECG interpretable and able to exercise	I (2)
<i>Evaluation of chest pain syndrome (use of MR coronary angiography)</i>	
Intermediate pretest probability of CAD ECG interpretable and able to exercise	I (2)
Intermediate pretest probability of CAD ECG uninterpretable or unable to exercise	I (2)
High pretest probability of CAD	I (1)
<i>Evaluation of intracardiac structures (use of MR coronary angiography)</i>	
Evaluation of suspected coronary anomalies	A (8)
<i>Acute chest pain (use of vasodilator perfusion CMR or dobutamine stress function CMR)</i>	
Intermediate pretest probability of CAD No changes on the ECG and negative serial cardiac enzyme assays	A (7)
High pretest probability of CAD ECG—ST-segment elevation and/or positive cardiac enzymes	I (1)
Risk assessment with previous test results (use of vasodilator perfusion CMR or dobutamine stress function CMR)	
Coronary angiography (catheterization or CT) Stenosis of unclear significance	A (7)
Equivocal results on stress testing (exercise, stress SPECT, or stress echocardiography) Intermediate CHD risk (Framingham)	U (6)
Normal findings on previous stress testing (exercise, nuclear imaging, echocardiography, MRI) High CHD risk (Framingham) Within 1 year of previous stress test	I (2)

TABLE 17G-1 Joint Professional Society Evaluation of Appropriate Indications for Cardiac Magnetic Resonance Imaging—cont'd

INDICATION	APPROPRIATENESS (MEDIAN SCORE)
Risk assessment: preoperative evaluation for noncardiac surgery	
<i>Low-risk surgery (use of vasodilator perfusion CMR or dobutamine stress function CMR)</i>	
Intermediate perioperative risk predictor	I (2)
<i>Intermediate- or high-risk surgery (use of vasodilator perfusion CMR or dobutamine stress function CMR)</i>	
Intermediate perioperative risk predictor	U (6)
Detection of CAD: postrevascularization (PCI or CABG)	
<i>Evaluation of chest pain syndrome (use of MR coronary angiography)</i>	
Evaluation of bypass grafts	I (2)
History of percutaneous revascularization with stents	I (1)
Structure and function	
<i>Evaluation of ventricular and valvular function*</i>	
Assessment of complex congenital heart disease, including anomalies of coronary circulation, great vessels, and cardiac chambers and valves Procedures may include determination of LV-RV mass and volumes, MRA, quantification of valvular disease, and contrast enhancement	A (9)
Evaluation for arrhythmogenic right ventricular cardiomyopathy (ARVC) Patients presenting with syncope or ventricular arrhythmia	A (9)
Evaluation of LV function after myocardial infarction or in patients with heart failure Patients with technically limited images on the echocardiogram	A (8)
Quantification of LV function Discordant information from previous tests that is clinically significant	A (8)
Evaluation of specific cardiomyopathies (infiltrative [amyloid, sarcoid], HCM, or that caused by cardiotoxic therapies) Use of delayed enhancement	A (8)
Characterization of native and prosthetic cardiac valves, including planimetry of stenotic disease and quantification of regurgitant disease Patients with technically limited images from echocardiogram or TEE	A (8)
Evaluation of myocarditis or myocardial infarction with normal coronary arteries Positive cardiac enzyme assays without obstructive atherosclerosis on angiography	A (8)
Evaluation of LV function after myocardial infarction or in patients with heart failure	A (7)
<i>Evaluation of intracardiac and extracardiac structures</i>	
Evaluation of cardiac mass (suspected tumor or thrombus) Use of contrast for perfusion and enhancement	A (9)
Evaluation of pericardial conditions (pericardial mass, constrictive pericarditis)	A (8)
Evaluation for aortic dissection	A (8)
Evaluation of pulmonary veins before radiofrequency ablation for atrial fibrillation Left atrial and pulmonary venous anatomy, including dimensions of veins for mapping purposes	A (8)
Detection of myocardial scar and viability	
<i>Evaluation of myocardial scar (use of late gadolinium enhancement)</i>	
To determine viability before revascularization Viability assessment by SPECT or dobutamine echocardiography has provided "equivocal" or "indeterminate" results	A (9)
To determine viability before revascularization To establish likelihood of recovery of function with revascularization (PCI or CABG) or medical therapy	A (9)
To determine the location and extent of myocardial necrosis, including no-reflow regions Post-acute myocardial infarction	A (7)
To detect post-PCI myocardial necrosis	U (4)

A = appropriate; CABG = coronary artery bypass grafting; CAD = coronary artery disease; CHD = congenital heart disease; CMR = cardiovascular magnetic resonance [imaging]; CT = computed tomography; ECG = electrocardiogram; HCM = hypertrophic cardiomyopathy; I = inappropriate; LV = left ventricular; MRI = magnetic resonance imaging; PCI = percutaneous coronary intervention; RV = right ventricular; SPECT = single photon emission computed tomography; TEE = transesophageal echocardiography; U = uncertain.

*The Joint Professional Society comprises the American College of Cardiology Foundation, American College of Radiology, Society of Cardiovascular Computed Tomography, Society for Cardiovascular Magnetic Resonance, American Society of Nuclear Cardiology, North American Society for Cardiac Imaging, Society for Cardiovascular Angiography and Interventions, and Society of Interventional Radiology.

†Procedures may include LV and RV mass and volumes, MR angiography, quantification of valvular disease, and delayed contrast enhancement.

From Hendel RC, Patel MR, Kramer CM, et al: ACCF/ACR/SCCT/SCMR/ASNC/NASCI/SCAI/ SIR 2006 appropriateness criteria for cardiac computed tomography and cardiac magnetic resonance imaging: a report of the American College of Cardiology Foundation Quality Strategic Directions Committee Appropriateness Criteria Working Group, American College of Radiology, Society of Cardiovascular Computed Tomography, Society for Cardiovascular Magnetic Resonance, American Society of Nuclear Cardiology, North American Society for Cardiac Imaging, Society for Cardiovascular Angiography and Interventions, and Society of Interventional Radiology. *J Am Coll Cardiol* 48:1475, 2006.

The panel stressed that appropriate use criteria (AUC) are not substitutes for sound clinical judgment and practice experience. Medical reasons may preclude application of these criteria to specific patients, and clinician judgment should be used at all times in applying the criteria. For example, the rating of an indication as inappropriate should not dissuade a provider from performing CMR imaging when patient- and condition-specific data support that decision, and not performing a study rated as appropriate may be the correct decision in light of unique patient, clinical, and other relevant information.

The current AUC methodology² has changed the nomenclature such that ratings of 1 to 3 are now termed “rarely appropriate,” rather than “inappropriate,” and ratings of 4 to 6 are now termed “may be appropriate.” Ratings of 7 to 9 remain “appropriate.” However, the AUC for CMR have not yet been updated to reflect this change in terminology. The recent AUC documents for multimodality imaging in stable ischemic heart disease and heart failure^{3,4} do conform to the updated terminology and provide criteria for use of CMR in these conditions relative to the applications of the other imaging modalities (see Chapter 20, Guidelines).

Progress in the clinical capabilities of cardiovascular computed tomography (CT) provides an array of applications for noninvasive cardiac and coronary artery assessment. Cardiac CT angiography now provides excellent image quality at low to extremely low effective radiation doses, which, coupled with ongoing progress in scanner technology and accumulating clinical trial evidence, establishes CT as a core technology for cardiovascular patient care. Beyond CT angiography, the technique now provides detailed assessment of the arterial wall, left ventricular (LV) and right ventricular (RV) systolic function, and cardiac valve morphology. It also enables myocardial tissue characterization and evaluation of coronary physiology with perfusion imaging. Together, these capabilities provide comprehensive evaluation of cardiac structure and function in appropriately selected patients (Videos 18-1, 18-2, and 18-3).

The basic principle of CT technology harnesses ionizing radiation within a gantry rotating around the patient in which x-rays are detected on a detector array (**Fig. 18-1**) and converted through reconstruction algorithms to images. Physical limits to spatial and temporal resolution are recognized, based on minimum detector width for detection of radiation signals and the speed at which the gantry can physically rotate. These physical limits are now being surmounted through software enhancements enabling preservation of or even improvements in diagnostic image quality at lower radiation exposures. The timeline of technical progress in CT between 1991 and approximately 2011 depicted in **Figure e18-1** summarizes the major technical advances including the increasing growth in the number of detector rows (or “slices”). Each row is a narrow channel, approximately 0.625 mm in width for “standard” width detectors, through which x-rays are detected on scintillation crystals. The number of detector rows aligned in an array has increased from one in single-detector units to 4, 16, 64, and ultimately 256 to 320 rows in “wide-area” detectors. The increase in the number of rows leads to wider coverage, with more of the heart viewed simultaneously—up to 16 cm in a single gantry rotation for 320 detector rows at a width of 0.625 mm each (**Table 18-1**)—leading to shorter scan acquisition times and consequently reduced radiation exposure and contrast requirements. Spatial resolution within the imaging plane (the x-y axis) is broadly determined by the detector width, and the ability to create volumes of image data (voxels) of equal sides on all size, or *isotropism*. At present, the narrowest commercial detector width is 0.32 mm, for “high-definition” CT. The other major constraint with cardiac imaging is temporal resolution, a crucial factor in obtaining motion-free cardiac images. To achieve this requires fast gantry rotation (at present, maximum gantry rotation times are approximately 270 to 330 milliseconds) and performing image acquisition or reconstruction during periods of limited cardiac motion (end-systole to mid-late diastole). At present, CT spatial resolution through reconstruction of overlapping data sets is approximately 0.5 mm³, and temporal resolution is approximately 83 to 165 milliseconds achieved with use of half-scan reconstruction techniques, in which data from

50% of the gantry revolution are used for image reconstruction. Further refinements in spatial resolution are possible with the use of narrower detector widths (below 0.625 mm—high-definition CT) and through the addition of iterative image reconstruction techniques. Improvements in temporal resolution have been obtained through novel scanner designs (e.g., dual-source CT, in which simultaneous imaging with two-source detector arrays leads to temporal resolutions of 70 milliseconds through quarter-scan reconstruction), but physical forces from the weight of the rotating gantry will make further clinically important improvements difficult. Although the temporal and spatial resolution of cardiac CT (approximately 0.23 to 0.4 mm) remains less than that of invasive coronary angiography (<0.1 mm), it is sufficient for highly accurate, diagnostic coronary artery imaging.

SCAN MODES

The two basic scan modes in cardiac CT, helical and axial scanning (**Fig. 18-2**), are now available in a variety of combinations permitting a high degree of clinical flexibility (**Table 18-2**).¹ *Helical* scanning involves continuous radiation exposure and table movement (the patient is moved through the rotating x-ray beam) during which the detector arrays receive projection data from multiple contiguous slices of the patient. This scan mode relies on collection of a redundant or overlapping data set so that complete image data can be reconstructed after CT data acquisition (“retrospective” reconstruction). The reconstruction of CT data to images relies on aligning the data to the electrocardiogram (ECG) and then selectively including only CT data from the desired time point of the ECG (typically when cardiac motion is at a minimum, so that cardiac structures are in a consistent position within the chest). A newer scan mode, high-pitch helical CT,² uses a very rapid rate of table feed (for movement of the patient through the x-ray beam) in a single cardiac cycle, enabling ultra-low-dose acquisitions by virtue of very short exposure times (approximately 250 milliseconds). This scan mode must be performed only in optimally prepared patients with controlled heart rate and requires specific technology (dual-source CT).

By contrast, *axial* imaging involves sequential scanner “snapshots,” in between which the x-ray tube is turned off and the table is moved to a different position for the next image to be acquired. The CT data are then reconstructed in a series of slices, akin to slices of a loaf of bread.

The major relative merit of helical CT acquisition is the ability to reconstruct data throughout the cardiac cycle, enabling great flexibility for cine evaluation of ventricular function and data editing in the event of cardiac arrhythmias. The major relative merit of axial CT acquisition is the “on/off” x-ray exposure, with consequent marked (68%) reductions in radiation exposure but with limitations in data reconstruction, including the relative inability to evaluate ventricular function unless the study is performed using a widened acquisition window during systole. Both modes produce images of similar spatial and temporal resolution (determined by physical limits of the scanner technology) and thus provide the same diagnostic image quality, as demonstrated in the PROTECTION I clinical trial.³

VIDEO 18-2

CT ventriculogram in a 60-year-old woman with mitral valve prolapse and mitral annular calcification. **A**, the two-chamber view demonstrates bileaflet prolapse with calcification of the posterior mitral annulus. **B**, The annular calcification is also apparent in the three-chamber view. **C**, It is particularly prominent in the short-axis view.

VIDEO 18-3

CT ventriculogram in a 58-year-old man with combined aortic regurgitation and mitral regurgitation. **A**, Three-chamber view. **B**, Four-chamber view. There is no evidence of important valvular calcification; however, there is evidence of incomplete coaptation of the mitral leaflets in the four-chamber view. **C**, The aortic valve is also well visualized, demonstrating incomplete closure of the leaflets. **D**, The mitral valve is also well visualized in the short-axis view.

FIGURE 18-1 View within the rotating multidetector CT gantry. Key elements include the x-ray tube or source, a collimator to align the x-ray beam, and the detector array, consisting of narrow channels for detection of x-ray photons. The number of detector channels determines the nomenclature (e.g., 64-row multidetector CT). At present, the maximum number of detectors within a commercially available multidetector CT scanner is 320.

FIGURE 18-2 Helical and axial CT scan acquisition modes.

TABLE 18-1 Evolution of Common Multidetector Computed Tomography Technical Parameters

	4-ROW	16-ROW	64-ROW	320-ROW
Temporal resolution (half-scan reconstruction)	250 msec	210 msec	165 msec	175 msec
Spatial resolution	1.25 mm	1 mm	0.4 mm	0.4 mm
Volume coverage	0.5-3 cm	1-2 cm	2-4 cm	15 cm
Breath-hold	30-40 sec	20 sec	10 sec	2 sec

TABLE 18-2 Scanning Modes for Cardiac Computed Tomography

FEATURE	SCAN MODE			
	Helical, Low Pitch	Axial, Prospectively ECG-Triggered with 64-Slice CT	Axial, Prospectively ECG-Triggered with Wide-Area Detector	Helical, High Pitch, Prospectively ECG-Triggered
Synonym(s)	Spiral, retrospectively gated	Triggered, step and shoot	Triggered	High-pitch helical
Basic principle	X-ray tube continuously "on," with patient moved through the beam	X-ray tube "on" and "off" triggered by the ECG, with no scanning between steps as the patient is moved through the scan range	Acquisition of CT data during a single heartbeat	X-ray tube "on" only for a single heartbeat during rapid helical acquisition without significant data overlap
CT data acquired	Systole and diastole	Set phase (diastole or systole) with some phase tolerance (temporal padding)	Set phase (diastole or systole) with some phase tolerance (temporal padding)	Can include systole and diastole for LVEF determination
Radiation-sparing maneuvers	ECG-based tube current modulation, limited scan length, use of 100 kVp in smaller patients	Limited scan length, use of 100 kVp in smaller patients	Single versus 2- or 3-beat scanning	Use of 100 kVp in smaller patients
Advantages	Enables flexible reconstruction in the event of arrhythmias or artifacts Evaluation of cine images for systolic and diastolic frames (ejection fraction)	Low radiation dose, no loss in image quality for purpose of coronary or structural diagnosis	Temporal uniformity of contrast and absence of alignment artifacts	Extremely low radiation exposure
Disadvantage	Higher radiation dose	Loss of ventricular function evaluation	Less applicable to high heart rates or arrhythmias	Dual-source CT only, in patients with low and stable heart rate
Uses	Patients who do not qualify for prospectively triggered CT	Standard methodology for patients with low, regular heart rates	Wide-area detectors only	Dual-source CT only

LVEF = left ventricular ejection fraction.

Following data acquisition, images are reconstructed within the desired field of view (encompassing cardiac structures) including thin slices (for evaluation of coronary arteries and finer cardiac details), data at different time points of the cardiac cycle (to provide flexibility for resolution of motion artifacts), and thicker slices (for evaluation of cardiac chambers and noncardiac anatomy). Reconstructions may be performed using selected reconstruction "kernels," which are mathematical algorithms for blending data from adjacent voxels resulting in images with either sharp or smooth detail (Fig. 18-3). A major recent advance has been the advent of adaptive statistical iterative reconstruction techniques as an alternative to the traditional approach of filtered back-projection. Although various techniques are used by different CT manufacturers, the basic principle is to reconstruct images by fully modeling the system statistics in an iterative fashion, enabling improved noise properties without sacrificing image quality.

This iterative approach enables scanning at lower radiation exposure (30% to 40%) without any degradation in image quality.⁴ Opportunities include applying iterative reconstruction techniques to further reduce radiation exposure, and to optimize evaluation of challenging scans, such as those showing high levels of coronary calcium, in which improved accuracy has been reported, increasing from 92% with use of filtered back-projection, to 96% with iterative reconstruction.

RADIATION EXPOSURE

Radiation dosing is measured using the CT dose index (CTDI) and dose-length product (mGy • cm). Determination of effective radiation dose (in sievert [Sv] units) entails the application of a constant determined by the relative radiation sensitivity of the tissue. The weighting factor for the chest is 0.14. Radiation exposure must be kept to the minimum achievable that retains diagnostic image quality. Factors

FIGURE 18-3 Reconstruction of CT data using two different reconstruction “kernels.” In **A**, a soft or smoothing reconstruction kernel is used. By comparison, the sharp kernel in **B** produces a more grainy image. The sharp kernel results in an image with more edge definition between high- and low-attenuation material or structures such as coronary calcium.

TABLE 18-3 Methods to Limit Radiation Exposure

- Select appropriate patients for imaging. Avoid inappropriate testing indications.
- Consider need for coronary calcium scanning—omit if information obtained unlikely to add to the patient assessment. If calcium score very high, reconsider appropriateness of coronary CT angiography.
- Limit scan length (z axis) to cardiac structures/essential structures to include in scan.
- Tailor scanner settings:
 - Tube current: mA (weight-based)—may reduce with use of adaptive statistical iterative reconstruction
 - Tube output: kVp (100 kVp for patients <80 kg)
- Acquisition parameters
 - Scanning method:
 - Use axial scanning when ventricular functional information not needed.
 - Helical scans: use tube current modulation minimizing the proportion of scanning time at full tube current.

determining radiation exposure (Table 18-3) include the volume of tissue scanned (scan length in the z axis of the patient), scanner settings including the tube current (mA) and tube voltage output (peak tube voltage, or kVp), and the amount of overlap in the data acquired (pitch). Scanner programming including helical or axial scanning, also is very important. Helical scanning optimally includes the use of upward modulation of the tube current (Fig. 18-4) during desired imaging periods (e.g., mid-late diastole) and downward modulation of the tube current during periods of cardiac motion (e.g., systole and early diastole). The use of “tube current modulation” can eliminate 25% to 40% of radiation dosage.⁵ Radiation exposure increases directly with tube current, and in accordance with the square of peak tube voltage. Reduced tube voltage is therefore especially important for limiting radiation exposure. Because 100 kVp imaging leads to a 40% radiation sparing without any degradation in image quality,⁶ nonobese patients should preferentially be scanned using this tube voltage. Axial scan protocols at 100 kVp can be performed at effective radiation doses of below 4 mSv, an amount equivalent to approximately 1 year of normal background radiation. Continuing this trend

toward reduced tube voltage imaging, even further dose reductions (80% compared with 120 kVp imaging) with retained diagnostic image quality can be achieved using 80 kVp imaging.⁷ Recent data on coronary CT angiographic imaging at 80 kVp using a high-pitch, prospectively ECG-triggered scan mode in patients with normal body mass index show mean radiation exposures of 0.4 mSv, or the equivalent of four chest x-ray examinations.⁸ In the aggregate, this represents a 20- to 50-fold reduction in potential radiation exposure in less than a decade of technical progress in cardiac CT. Future efforts must focus on greater application of potential dose-sparing techniques, because current data indicate a large degree of regional variation in radiation exposure, which in part arises as centers gradually upgrade CT equipment but also reflects response to physician education. The Michigan CT registry showed dose reductions of greater than 50% within 1 year in Michigan through a combination of education and payment incentives.⁹

PATIENT PREPARATION AND SCANNING SEQUENCE

The absolute requirements for patients to undergo contrast-enhanced cardiac CT angiography include the ability to receive intravenous contrast and cooperate with breathing instructions and hold their breath for the duration of the scan (typically 10 seconds or less, depending on scan length in the Z axis and acquisition mode). Relative contraindications include high or irregular heart rates (particularly atrial fibrillation), morbid obesity, or severe coronary artery calcium (CAC), defined as CAC scores above 400 to 1000. Each of these conditions can degrade scan quality or interpretability. These relative contraindications continue to be partially surmounted by technical advances in the field. High heart rates (addressed using dual-source scanners or multisegment reconstruction techniques), irregular heart rates (arrhythmia rejection software), atrial fibrillation (prospective ECG-triggered acquisitions), morbid obesity, and CAC (iterative reconstruction techniques) each can be partially overcome through recent advances in CT technology. Patient instructions include pretest, on-site, and post-test considerations (summarized in Table e18-1). Most centers control heart rate using beta blockers administered either orally (e.g., metoprolol 25 to 100 mg 1 hour before the scan) or intravenously (e.g., metoprolol 5 mg in repeated doses) to achieve a resting heart rate less than

FIGURE 18-4 Helical CT acquisition with dose modulation in which the timing of increased tube current from 20% to 100% of maximum output is synchronized with the electrocardiogram (diastole). This correlation limits the period of exposure to maximum tube current (250 milliseconds) and results in lower radiation exposure to the patient without loss of image quality for diastolic image reconstruction.

TABLE e18-1 Patient Instructions and Preparation for Cardiac Computed Tomography

Pretest	<ul style="list-style-type: none"> • No food 3 hours before examination • No caffeine 12 hours before examination • Drink water • Take all regular medications • Take premedications for contrast allergy as needed • Take premedications for renal protection as needed • Serum creatinine by institutional protocol (diabetics, age >60 years, known chronic kidney disease)
On-site preparation	<ul style="list-style-type: none"> • Intravenous line—8 or 20 gauge, antecubital site • Pulse/blood pressure/ECG monitor • Beta blocker (IV or PO) (metoprolol) <ul style="list-style-type: none"> – 25-100 mg metoprolol PO 1 hour before scan – 5 mg metoprolol intravenous bolus; repeat as needed • Positioning • Breath-hold training—observe heart rate response • Nitroglycerin—400-800 µg sublingual
Post-test	<ul style="list-style-type: none"> • Liberal oral fluids • Hold metformin 48-72 hours after contrast administration

65 beats/min. Some scanners with faster gantry rotations or dual-source configurations can obtain diagnostic image quality at higher heart rates, but in general scan quality is lower at higher heart rates.¹⁰ Nitroglycerin (400 to 800 µg sublingually) typically is administered just before CT angiography, to increase coronary artery diameter and improve the signal-to-noise ratio. Screening subjects for contraindications to nitrates such as phosphodiesterase inhibitors (e.g., sildenafil) should be routine.

Intravenous contrast is required for the performance of cardiac CT angiography. The principle is to achieve a plateau of contrast concentration in the coronary arteries that is sustained through the image acquisition to ensure uniform contrast opacification. A standard three-phase injection protocol consists of administration of undiluted contrast, 40 to 60 mL, at a rate of approximately 5 mL/sec through an antecubital 18 to 20 gauge intravenous line, followed by a smaller volume of dilute contrast (50:50 contrast-to-saline ratio, for a total of 10 to 20 mL), and then a bolus of saline (40 mL). The intent is to maximize contrast enhancement of the left side of the heart and arterial structures, with mild contrast enhancement of the right side of the heart and pulmonary artery. Excessive right-sided contrast enhancement can interfere with evaluation of the right coronary artery and is unnecessary for most scan indications (unless right-sided heart enhancement is judged necessary for the particular clinical indication) (Fig. 18-5). Timing of the scan in relationship to the contrast bolus is commonly performed using the triggered bolus method, in which contrast attenuation in the pulmonary artery or aorta is monitored, followed by automated scan initiation once an adequate CT attenuation value (110 to 180 Hounsfield units [HU]) is achieved. An alternative method is to tailor scan timing as determined using a contrast test bolus to determine the time to peak contrast attenuation, with subsequent scan programming based on the individual patient's transit time (which can vary from patient to patient in accordance with volume status, cardiac output, and ventricular/valvular function). After peak contrast opacification is attained, an additional delay including a patient breath-hold is programmed to last typically 6 to 10 seconds, to permit even contrast opacification of the coronary circulation and stabilization of heart rate. Scan time is determined by the scanner, acquisition mode, heart rate, and scan length in the Z axis, but for 64-row multidetector CT it is approximately 6 seconds. A typical sequence of scan acquisition and a postprocessing algorithm are shown in Table 18-4 and Table e18-2, respectively. Novel applications, such as evaluation of late myocardial enhancement, or myocardial perfusion during vasodilator stress, require specific alterations to the imaging protocol.

FIGURE 18-5 Timing of arrival of radiocontrast medium within the right side of the heart. In **A**, timing was early because contrast was still contained within the right atrium and right ventricle (asterisk). This may be desirable if delineation of right-sided cardiac structures is necessary, but in general, cardiac CT usually is timed after contrast has passed through the right side of the heart, leading to a levo-phase image, as shown in **B**.

TABLE 18-4 Typical Cardiac Computed Tomography Scan Sequence

1. Scout film	Determine cardiac location
2. Set scan range	Limit scan range to cardiac and other relevant structures of interest
3. Calcium scan	If indicated: use calcium scan to refine CT angiography scan range
4. Nitroglycerin administration	400-800 µg sublingual
5. Contrast test bolus or bolus tracking	Contrast injection to determine transit time or track bolus until scan is initiated with achievement of attenuation threshold
6. Breath-hold initiated	Permits contrast opacification to become uniform, and heart rate to stabilize; prolonged scan delays may lead to increased coronary venous opacification
7. CT angiogram	Check vital signs after procedure
8. Image reconstruction and postprocessing/analysis	Use of interpretation and reporting standards recommended

CARDIAC COMPUTED TOMOGRAPHY ANATOMY

Thin-slice cardiac CT reconstructions with isotropic voxels can be displayed in any imaging plane with minimal to no image distortion. Cardiac chambers, coronary vessels, great vessels, and other surrounding cardiac and mediastinal structures can be imaged in a multiplanar fashion (Fig. 18-6). Images can be displayed in orthogonal planes (axial, coronal, sagittal) or nonstandard planes (oblique planar reformats) (Fig. 18-7). Images are evaluated in both thin- and thick-slice projections, most commonly using a maximal-intensity projection in which the pixel within the slab volume with the highest Hounsfield number is viewed. Maximum-intensity projections provide the ability to view more structures within a single planar view but can obscure details, particularly when highly attenuating structures (such as CAC) are present. Optimal accuracy for cardiac CT entails the use of an interactive evaluation technique in which optimal imaging planes are selected by the interpreter.¹¹ Curved structures can be viewed in a planar fashion by means of curved multiplanar

reformatations (see Fig. 18-7), constructed with the use of centerline techniques. Volume-rendered reconstructions are useful for revealing general structural relationships but not for viewing details of the coronary anatomy. In addition to image planes for coronary artery evaluation, which can be categorized using coronary segmentation models (Fig. 18-8), analysis of cardiac chambers is performed using standard short-axis and horizontal and vertical long-axis projections (Fig. 18-9). A complete evaluation includes inspection of the images for noncardiac pathologic processes in the lungs, mediastinum, and great vessels.

CLINICAL INDICATIONS

Clinical indications for cardiovascular CT encompass a broad range of potential anatomic imaging targets

TABLE e18-2 Typical Reconstruction Parameters for Cardiac CT

Coronary anatomy	<ul style="list-style-type: none"> • Half-scan reconstruction • Field of view 200-250 mm • Slice thickness 0.5-0.6 mm • Slice increment 50% • Reconstruction phases: <i>diastole</i>: 70%-80% of the RR interval most common; <i>end-systole</i> (40% phase): if high heart rates/helical acquisition • Semisharp reconstruction kernel
Coronary calcium	<ul style="list-style-type: none"> • Field of view 200-250 mm • Slice thickness 2.5-3.0 mm
Ventricular function	<ul style="list-style-type: none"> • Field of view 200-250 mm • Slice thickness 2.5 mm • Reconstruction phases: 0-90% in 5%-10% increments
Noncardiac evaluation	<ul style="list-style-type: none"> • Full field of view • Slice thickness 5 mm

and clinical scenarios. These can be broadly divided into seven categories: detection of coronary artery disease (CAD) in symptomatic patients without known heart disease, CAD risk assessment in asymptomatic patients, CAD detection in other cardiac conditions, use of CT angiography after other test results, evaluation after revascularization, evaluation of cardiac structure and function, and evaluation of intracardiac and extracardiac structures. In general, coronary CT angiography is considered most appropriate in which the pretest likelihood of CAD is low or intermediate, and in which the test results would contribute to improved patient management. Paralleling the rapid technical development of cardiac CT technology over the past decade, increasing numbers of clinical trials guide optimal use of cardiac CT, particularly in the setting of chest pain in the emergency department. Use of cardiac CT also is guided by available data and expert opinion through multisociety appropriate use criteria, originally drafted in

2006¹² and revised in 2010.¹³ Use of cardiac CT is judged to be appropriate when the value of the expected incremental information, combined with clinical judgment, exceeds the expected negative consequences by a sufficiently wide margin for a specific indication that the procedure is generally considered acceptable care and a reasonable approach for the indication. Appropriate cardiac CT indications in the 2010 update are discussed in detail at the end of this chapter. Clinical trials are needed both to assess the clinical performance of cardiac CT relative to other techniques and to demonstrate its overall effect on net health outcomes. As is typical of other non-invasive cardiac imaging modalities, data show that selecting appropriate patients for cardiac CT can be directed through physician education. The Advanced Cardiovascular Imaging Consortium study conducted at 47 Michigan hospitals showed a reduction in rate of performance of inappropriate cardiac CT studies from 14.6% to 5.8% with provider education and reimbursement incentives.¹⁴ In this experience, the present cardiac CT appropriate use criteria led to classification in 92% of potential indications, although periodic update of the criteria remains essential.

Coronary Artery Calcium Scanning

CAC testing is used in asymptomatic patients to refine their clinically predicted risk of incident coronary heart disease (CHD) beyond that predicted by standard cardiac risk factors. CAC typically is present in amounts directly proportional to the overall extent of atherosclerosis, although typically only approximately 20% of plaque contains calcified regions. Arterial calcification is an active process involving the deposition of hydroxyapatite, most typically in areas with healed plaque rupture. Acute plaque ruptures and vulnerable plaques primarily contain speckled or fragmented calcium, whereas healed plaque ruptures most commonly are composed of diffuse calcium (Fig. 18-10). Although most clinical data regarding CAC were derived using electron beam CT, multidetector CT has supplanted electron beam scanning given the comparability of clinical scoring and the more widespread availability of the technology. CAC is detected using a standardized protocol involving prospective ECG-triggered axial scanning, with a slice thickness of 2.5 mm.¹⁵ Standard tube voltage is 120 kVp, with tube current set at 120 to 150 milliamperere-seconds (mAs), which should result in acceptably low levels of radiation exposure (1 to 2 mSv). CT CAC quantification primarily involves the measurement of the area and density of all foci of calcification, defined using a Hounsfield threshold of 130 HU (Fig. 18-11). The sum of the area and density weightings across the coronary arteries is the unitless “CAC score.” Based on the screening nature of CAC scanning for asymptomatic subjects, use of radiation-sparing techniques is paramount for patient safety. Proposed revised protocols include the use of a peak tube current of 100 kVp, which reduced radiation exposure down to approximately 1 mSv, but such protocols would require alteration of the HU threshold for calcium.¹⁶ Alternatively, reduced tube current (85 mAs) can be applied, leading to similar 40%

FIGURE 18-6 Overview of cardiac CT cross-sectional anatomy from axial images. **A**, Thin-slice axial projection at the level of the superior vena cava (SVC) and RV outflow tract (RVOT) showing relationships of the structures at the base of the heart. **B**, Thick-slice axial maximum-intensity projection showing the origin of the left main coronary artery (LMCA) and the left anterior descending coronary artery (LAD) (arrow). **C**, Midlevel four-chamber ventricular view showing the RA, RV, LA, and LV and the normal pericardium (Pc) (arrow). **D**, Thick-slice maximum-intensity projection showing the distal right coronary artery (RCA) and the nearby coronary sinus (arrow). Ao = aorta; LA = left atrium; LV = left ventricle; PV = pulmonary vein; RA = right atrium; RAA = right atrial appendage.

LAD = left anterior descending coronary artery; L-PDA = left posterior descending artery; L-PLB = left posterolateral branch; RCA = right main coronary artery; R-PDA = right posterior descending artery; R-PLB = right posterolateral branch.

FIGURE 18-9 Standard cardiac chamber axes on cardiac CT including two-chamber (A), four-chamber (B), and short-axis (C) views. Contrast timing in this study shows a typical level phase (right side of the heart is underfilled with contrast) in diastole (mitral valve is in the open position).

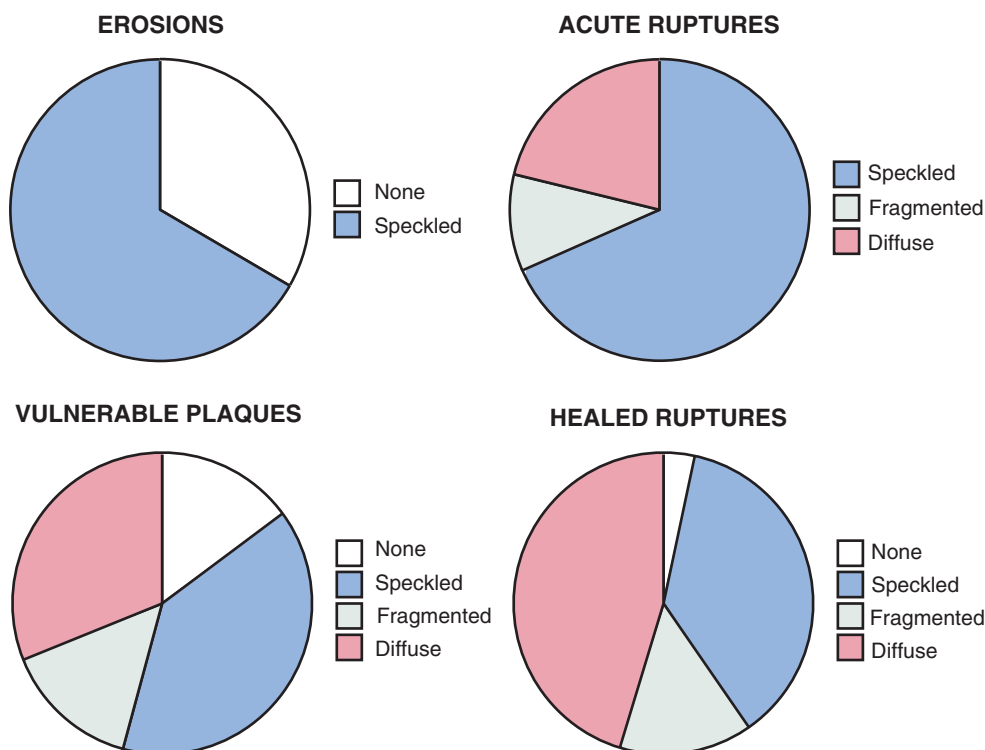

FIGURE 18-10 Diffuse calcified elements are present most commonly within plaques with healed areas of rupture and least commonly in plaque erosions. Small foci of calcification (speckled elements) are the dominant form of plaque element in vulnerable plaques and acute plaque ruptures. (From Burke AP, Taylor A, Farb A, et al: Coronary calcification: Insights from sudden coronary death victims. *Z Kardiol* 89[suppl 2]:49, 2000.)

FIGURE 18-11 Example of coronary artery calcium scoring from a noncontrast CT (left panel) in which calcified foci are identified (right panel) within the left anterior descending (orange) and left circumflex (pink outlined in blue) coronary arteries. The region's area (R-Ar) and its average density in HU (R-Av) are displayed and used in the area-density calcium scoring calculation.

reductions in radiation exposure, but without the need to alter the calcium HU threshold. CAC score reproducibility is modest, with interscan variability of 10% to 20%, being more reproducible at low heart rates and for higher CAC scores.

The presence and extent of CAC are dependent on age, sex, ethnicity, and standard cardiac risk factors. CAC scores are higher for age and sex among whites (Fig. 18-12).¹⁷ It is well established that the detection of CAC indicates an increased risk of incident CHD over that predicted by standard risk factors, ranging from 2-fold for scores of up to 100 to 11-fold for scores above 1000. Similar findings have been shown regarding sex and ethnicity in the Multi-Ethnic Study of Atherosclerosis (MESA) (see Fig. 18-12),¹⁸ and in both young (aged 40 to 50)¹⁹ and older²⁰ patient populations. Middle-aged women with any detectable CAC have an incident CHD event risk in excess of 2% per year.²¹ Recent data indicate that the spatial distribution of CAC may provide further risk stratification beyond the total calcium score. A "coronary CAC coverage score" was devised from the MESA and showed greater predictive accuracy for future CHD events than the area-density scoring system.²² This finding is in line with other observations that higher clinical risk is associated with multivessel CAC (for an equivalent score, three-vessel coronary CAC carries a worse prognosis than two- or one-vessel CAC),²³ the number of calcified lesions (the more lesions, the worse the prognosis),²⁴ and diffuse spotty calcified lesions (small foci <3 mm in size)²⁵ (Fig. 18-13). Conversely, data from 13 studies involving 75,000 patients over 4 years show that a CAC score of 0 is associated with a very high event-free probability (99.9%/year).²⁶

Based on the consistency of studies showing independent prediction of CHD risk, current appropriate use criteria support the use of CAC scanning as a risk stratification tool when an initial evaluation of clinical risk using risk prediction tools indicates an intermediate level of CHD risk (10% to 20% over 10 years, or in young patients with a low to intermediate risk, 6% to 10% over 10 years) or in low-risk patients with a family history of premature CHD.¹³ Comparisons of coronary CAC with lifetime risk estimates are needed. The National Cholesterol Education Program,²⁷ the 2010 guideline for assessment of cardiovascular risk in asymptomatic adults of the American College of Cardiology Foundation (ACCF),²⁸ and the ACCF/American Heart Association 2013 guidelines on the assessment of cardiovascular risk²⁹ indicate that CAC scanning is a reasonable testing option (Class 2A recommendation) among such patients, on the basis of the possibility that such patients might be

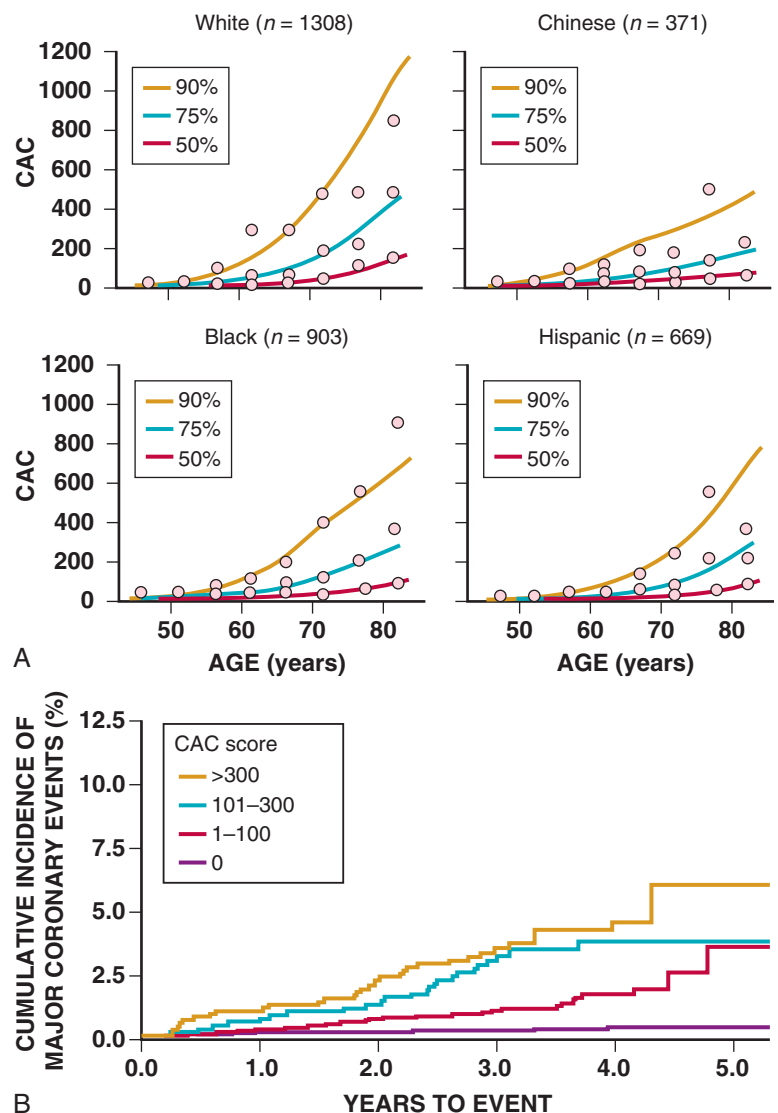

FIGURE 18-12 **A**, Data from MESA for the distribution of CAC scores among men relative to age and ethnicity. **B**, Major cardiovascular outcomes observed in MESA in association with higher thresholds of coronary calcium scores. (From McClelland RL, Chung H, Detrano R, et al: Distribution of coronary artery calcium by race, gender, and age: Results from the Multi-Ethnic Study of Atherosclerosis (MESA). *Circulation* 113:30, 2006; and Detrano R, Guerci AD, Carr JJ, et al: Coronary calcium as a predictor of coronary events in four racial or ethnic groups. *N Engl J Med* 358:1336, 2008.)

FIGURE 18-13 Distribution of coronary calcium on cardiac CT in four different patients: **A**, no detectable coronary calcium; **B**, coronary calcium in all three epicardial coronary arteries including (clockwise) the right coronary artery (arrow) and the left anterior descending and left circumflex coronary arteries; **C**, a "spotty" or diffuse pattern with multiple small (<3 mm) foci of coronary calcium; and **D**, a large calcified lesion in the left anterior descending coronary artery.

reclassified to a higher risk status based on high CAC score, with subsequent modification of patient management.

Online tools provide the ability to age/sex/ethnicity adjust CAC values, comparing patient data with population norms established in MESA (www.mesa-nhlbi.org). In addition, data from the MESA integrate CAC values with Framingham risk scores, leading to adjusted estimates for incident CHD. Risk estimates generally are revised downward for low CAC scores and upward for high CAC scores. Data from the MESA study show significant net reclassification improvement with both downward and upward classification of cardiovascular risk based upon CAC results.³⁰ Within initial risk strata, the range of risk varied from 2.5 to 20 fold dependent on the conditional presence or absence of CAC (see the case example in **Fig. e18-2**).

Community-based screening cohorts^{31,32} have shown up to three-fold greater use of aspirin and statin cholesterol medications and other proven cardiovascular risk reduction interventions in the setting of CAC. A single randomized trial did address the relationship between CAC screening guiding preventive therapy with statin.³³ Among participants of the St. Francis Heart Study with a CAC score above the 80th percentile ($n = 1005$), random assignment to atorvastatin treatment (20 mg/day) was associated with a 3% absolute risk reduction ($P = .08$) for composite cardiovascular events, and a significant 6.3% absolute risk reduction in those with a baseline CAC score above 400. Beyond recommendations for the provision of and adherence to risk-reducing therapies, an abnormal CAC scan in an asymptomatic patient can be associated with an increased likelihood of silent ischemia on stress myocardial perfusion imaging (see **Chapter 16**),^{34,35} and the absence of myocardial ischemia may moderate the event risk associated with a very high CAC score.³⁶ However, such testing is not recommended in the absence of clinical trial evidence showing patient benefit from such an approach.

The use of serial testing to define progression of CAC has been suggested as a method of further defining evolving CHD risk. Once present, CAC tends to progress at a rate of approximately 20%/year.³⁷ Middle-aged persons with a CAC score of 0 have an approximately 5%/year conversion rate from a zero to a nonzero score.³⁸ Although observational data from referred populations suggest that patients with clinically significant CAC progression (>15%/year) may have substantially higher clinical event risk for a given CAC score and a threefold increased risk for all-cause mortality,³⁹⁻⁴² risk-reducing interventions do not retard CAC progression, indicating that CAC progression is a complex phenomenon probably involving a mixture of both plaque healing and plaque progression.⁴³ Owing to concerns over radiation exposure, intertest variability, and undefined management implications, current guidelines do not support the performance of serial CAC testing; this remains an active area of investigation, however.¹⁷

Coronary Computed Tomography Angiography Diagnosis of Coronary Artery Disease

The primary clinical application of cardiac CT is the performance of noninvasive coronary CT angiography among patients with symptoms or suggestive evidence of myocardial ischemia. Meta-analysis of primarily single-center studies from symptomatic patients (prevalence of CAD 64%), shows the overall accuracy of 64-row CT angiography included a sensitivity of 87% to 99% and specificity of 93% to 96%.⁴⁴ Multicenter trials (**Table 18-5**)⁴⁵⁻⁴⁷ support data from single-center trials. More recent data acquired on newer

cardiac CT platforms such as dual-source CT or wide-area detectors confirm the accuracy of cardiac CT, along with improved performance, including reduced nonassessable coronary segments and image artifacts. Recent progress includes the application of cardiac CT to difficult patient populations such as those with atrial fibrillation⁴⁸ using either helical CT with retrospective ECG gating with a wide tube current modulation window (at the expense of high radiation exposure) or axial prospectively ECG-triggered acquisition using a temporal trigger typically 250 milliseconds from the preceding R wave to gather end-systolic data using either dual-source or wide-detector CT. Although atrial fibrillation remains a relative contraindication to cardiac CT, with appropriate technology and approach reasonable accuracy and diagnostic image quality can be achieved.

Accurate performance of cardiac CT requires proper attention to technical methods and patient preparation. Even under optimal conditions, however, some coronary segments (approaching 4%) will be uninterpretable because of patient or technical factors. Specificity will be reduced, particularly among patients with severe CAC (which can render CT angiography uninterpretable especially with CAC scores above 400 to 1000) or obesity (above approximately 40 kg/m², owing to excess image noise). Of note, most studies of accuracy of CT angiography are limited by selection of patients optimized for cardiac CT, and the analysis typically involves only the more proximal coronary segments down to approximately 1.5 mm in size.

The accuracy of cardiac CT angiography also must be considered in the context of the method of stenosis evaluation. The existing literature has primarily evaluated stenosis presence for detection of a 50% binary cutpoint. For routine clinical application, however, qualitative grading schemes have been proposed in which normal is distinguished from arteries with evident plaque with less than 25% (minimal), 25% to 49% (mild), 50% to 69% (moderate), 70% or greater (severe) stenosis (**Fig. 18-14**).⁴⁹ Compared with that graded using quantitative

FIGURE e18-2 The patient was a 59-year-old man who presented for periodic physical examination. He was active and asymptomatic. He had a history of dyslipidemia and borderline fasting glucose. Blood pressure is 135/89 mm Hg. Physical examination was normal. A lipid panel showed total cholesterol 179 mg/dL, LDL 83 mg/dL, and HDL 21 mg/dL. Fasting blood glucose was 101 mg/dL. Framingham risk score for 10-year CHD incidence was 12%, placing him in the intermediate-risk range. Given his intermediate level of cardiovascular risk, a coronary calcium scan was appropriately performed, showing a calcium score of 1101. By the MESA distributions, this placed him above the 90th percentile for age, sex, and ethnicity. His adjusted Framingham risk score using the MESA Arterial Age calculator was 30%. Although LDL was currently in the optimal range, his adjusted Framingham risk score reclassified him to the high-risk category (>20%), and atorvastatin 10 mg daily and aspirin 81 mg daily were begun. A program of diet and exercise was recommended to address the impaired fasting glucose. The patient was advised to be aware of chest pain or dyspnea as potential angina-equivalent symptoms; however, no additional evaluations were undertaken.

TABLE 18-5 Multicenter Trials Assessing the Diagnostic Accuracy of Cardiac CT Angiography for Detection of Coronary Artery Stenosis

STUDY	N	PREVALENCE OF CAD	SENSITIVITY	SPECIFICITY	POSITIVE PREDICTIVE VALUE	NEGATIVE PREDICTIVE VALUE

Miller et al.: CORE-64	291	56%	85	90	91	83

Data from Budoff MJ, Dowe D, Jollis JG, et al: Diagnostic performance of 64-multidetector row coronary computed tomographic angiography for evaluation of coronary artery stenosis in individuals without known coronary artery disease: Results from the prospective multicenter ACCURACY (Assessment by Coronary Computed Tomographic Angiography of Individuals Undergoing Invasive Coronary Angiography) trial. *J Am Coll Cardiol* 52:1724, 2008; Meijboom WB, Meijis MFL, Schuijff JD, et al: Diagnostic accuracy of 64-slice computed tomography coronary angiography: A prospective, multicenter, multivendor study. *J Am Coll Cardiol* 52:2135, 2008; and Miller JM, Rochitte CE, Dewey M, et al: Diagnostic performance of coronary angiography by 64-row CT. *N Engl J Med* 359:2324, 2008.

FIGURE 18-14 Coronary artery lesions of differing severity and grade as depicted on cardiac CT. **A**, Large mixed plaque without significant stenosis in the proximal left anterior descending coronary artery (curved multiplanar reformat), with outward arterial remodeling (arrow), as shown in the cross-sectional image (inset). **B**, Large noncalcified plaque with outward arterial remodeling in the right coronary artery with mild luminal stenosis (<25%). **C**, Moderate stenosis (50%) in the proximal left circumflex coronary artery with a mixed plaque (arrow). **D**, High-grade (>70%) stenosis of the mid-left anterior descending coronary artery with a noncalcified plaque (arrow). **E**, Total occlusion (arrow) of the distal left circumflex coronary artery.

invasive coronary angiography, CT angiographic stenosis severity tends to be somewhat worse, with only a modest correlation ($r = 0.5$ to 0.6), but the CT study correlates very well with intravascular ultrasound (IVUS), probably as a consequence of better visualization of the arterial wall.⁵⁰ As with results with invasive coronary angiography, the recognition of an anatomic stenosis is only modestly predictive of inducible ischemia. A 50% or greater stenosis on cardiac CT is associated with a 30% to 50% likelihood of demonstrable ischemia on myocardial perfusion imaging (see Chapter 16).^{51,52} underscoring the need for a multimodality approach to imaging to guide subsequent patient treatment. New methods combining coronary CT angiography with either vasodilator stress perfusion imaging or computational fractional flow reserve (FFR) measurements (see further on) may offer combined anatomic and physiologic CT assessment.

Prognosis of Coronary Artery Disease

Invasive angiographic studies of CAD established that increasing severities of coronary involvement are associated with less favorable prognosis. Two approaches have been studied, including calculation of a segment involvement score, and more simply according to the number of involved vessels. The segment stenosis score takes into account the segmental involvement of atherosclerosis based upon the number of coronary segments showing plaque and its severity. A more simple approach determines involvement as number of coronary arteries involved (one to three, and left main). By either approach, greater severity of coronary artery involvement is associated with a worse cardiovascular outcome, even exclusive of early revascularization procedures that may be precipitated by the test result. In the CONFIRM registry,⁵³ the annual risk-adjusted hazard ratio, relative to

that for normal coronary arteries, was 1.62 for nonobstructive CAD, 2.00 for one-vessel, 2.92 for two-vessel, and 3.70 for three-vessel or left main CAD (Fig. 18-15). Extending from these results, individuals studied with coronary CT angiography appear more likely to receive aspirin and statin preventative therapies.⁵⁴

Clinical Applications of Coronary Computed Tomography Angiography

Computed Tomography in the Emergency Department. Because of the high negative predictive value of cardiac CT, the test has been studied as a method to exclude CAD among patients presenting with acute chest pain. Three randomized clinical trials have examined cardiac CT among patients presenting to the emergency department with chest pain or ischemic equivalent symptoms.⁵⁵⁻⁵⁷ These studies (Table 18-6) typically enrolled patients at low likelihood of an acute coronary syndrome (ACS) based on ECG and biomarker findings. Compared with standard of care approaches with serial biomarkers and protocol or clinically selected testing, CT angiography uniformly led to more rapid triage or discharge times, with overall net equivalent cardiovascular outcomes. Cardiac CT criteria for admission to the hospital varied in the studies, with admission advocated for detection of greater than 25% stenosis. Most patients have normal

FIGURE 18-15 Data from the CONFIRM registry showing worse cardiovascular prognosis based on increasing severity of CAD, as defined by cardiac CT angiography. An adverse prognosis was noted for nonobstructive CAD, in addition to one-, two-, or three-vessel CAD. (From Min JK, Dunning A, Lin FY, et al: Age- and sex-related differences in all-cause mortality risk based on coronary computed tomography angiography findings: Results from the International Multicenter CONFIRM [Coronary CT Angiography Evaluation for Clinical Outcomes: An International Multicenter Registry] of 23,854 patients without known coronary artery disease. *J Am Coll Cardiol* 58:849, 2011.)

findings on CT angiograms and can be safely discharged, whereas approximately 20% to 50% may have some plaque identified and require further evaluation (see case study in Fig. e18-3).⁵⁸ An approach including cardiac CT leads to more correct diagnoses of CAD and less subsequent testing overall, but at a cost of more frequent invasive testing.⁵⁹ On the basis of this clinical trial evidence, coronary CT angiography received a recommendation as “appropriate” for patients at low and intermediate likelihood for having CAD.¹³

Detection of Noncalcified Plaque. Beyond detection of coronary stenosis or CAC, noncalcified plaque detection is an appealing but unvalidated approach to the risk assessment. Defined as any coronary arterial wall lesion with an x-ray attenuation detectably below that for the iodine contrast medium but higher than for surrounding tissue, noncalcified plaque is difficult to quantify, with limited accuracy and reproducibility for the techniques in use. Detection requires maximal spatial and temporal resolution and minimized image noise through higher radiation exposures. Compared with that for IVUS (see Chapter 20), the correlation coefficient for CT angiography in determining plaque volumes is approximately 0.69, with a sensitivity of approximately 80%.⁶⁰ In general, noncalcified plaque severity tends to be underestimated, particularly for small plaques. Among asymptomatic patients, noncalcified plaque frequently is found along with CAC but is present in only 5% to 10% of patients as the sole finding, and very infrequently in an obstructive pattern.^{60,61} For this reason, screening CT angiography is not advocated in asymptomatic patients for the purpose of detecting noncalcified plaque.

Among symptomatic patients, noncalcified plaque tends to be a common finding. Based on correlations with IVUS, plaques with low attenuation values (15 to 50 HU) tend to be morphologically classified as lipid-rich, and those with attenuation values of approximately 100 HU tend to be fibrous plaques. This finding has generated interest in noninvasive plaque characterization and quantification as a method to identify patients at greater risk for subsequent ACS. Plaque features proposed to be associated with greater risk for plaque rupture or ACS include low-attenuation plaque (plaque with attenuation values <30 HU), outward arterial remodeling (artery diameter ratio of the involved segment to a proximal reference of 1.1 or greater), and a spotty pattern (<3 mm in size) of calcification.²⁵ In particular, the presence of both low attenuation plaque and outward arterial remodeling (see Fig. 18-14) have been associated with increased risk (hazard ratio [HR], 23) of ACS.⁶² Problems with this assessment include the infrequent nature of these findings, as well as substantial overlap and the impact of scan technique on attenuation values. More validation work is needed to further elucidate the prognostic value of plaque characterization. Among patients with non-ST-segment elevation myocardial infarction (MI), quantitative CT angiographic plaque volume assessments using virtual IVUS techniques demonstrate an 18% increase in risk for subsequent events, with each 100 mm³ of plaque burden.⁶³ Emerging methods with high-definition CT with spatial resolution of approximately 0.3 mm may overcome some of the limitations of noncalcified plaque underdetection (Fig. 18-16).

Evaluation after Coronary Bypass Surgery. In general, patients with known CAD are not optimal candidates for CT angiography

TABLE 18-6 Randomized Controlled Trials Evaluating Clinical Outcomes with Use of Coronary Computed Tomography Angiography in the Emergency Department for Evaluation of Patients with Possible ACSs

STUDY	NO. OF SITES	TIMI RISK	NO. OF PATIENTS (WITH RANDOMIZATION RATIO)	LOS	30-DAY MACE	COST

*30-day MACE: not statistically significant.

[†]Cost: statistically significant.

[‡]CT-STAT trial reported time to diagnosis as opposed to total length of stay.

LOS = length of stay; MACE = major adverse cardiovascular events; N/A = data not available; TIMI = Thrombolysis In Myocardial Infarction [trial] (score).

Data from Goldstein JA, Chinnaiyan KM, Abidov A, et al: The CT-STAT (Coronary Computed Tomographic Angiography for Systematic Triage of Acute Chest Pain Patients to Treatment) trial. *J Am Coll Cardiol* 58:1414, 2011; Litt HJ, Gatsonis C, Snyder B, et al: CT angiography for safe discharge of patients with possible acute coronary syndromes. *N Engl J Med* 366:1393, 2012; and Hoffmann U, Truong QA, Schoenfeld DA, et al: Coronary CT angiography versus standard evaluation in acute chest pain. *N Engl J Med* 367:299, 2012.

FIGURE e18-3 Coronary CT angiogram of the right coronary artery showing outwardly remodeled noncalcified plaque. The patient was a 47-year-old woman who presented to the emergency department with a single episode of chest pain occurring at rest. She had no known risk factors but smoked one-half pack of cigarettes per day. Findings on physical examination, ECG, and an initial troponin assay were normal. Her pretest likelihood of CAD was assessed to be low on the basis of age and the presence of one cardiovascular risk factor. A prospectively ECG-triggered axial coronary CT angiogram was performed on a 256-slice scanner at 100 kVp. Effective radiation dose was 2.4 mSv. Images show a moderate, noncalcified plaque with outward remodeling in the right coronary artery (*gray material*, intermediate in attenuation between the coronary lumen and surrounding tissue), with CT densities ranging from 92 to 135 HU. Outward remodeling is evidenced by the overall greater coronary outer wall dimension (*bulge*) at the site of the lesion. The patient was admitted to the hospital for further evaluation.

because of the high pretest likelihood of coronary atherosclerosis. However, evaluation of coronary bypass graft patency is highly accurate, with sensitivities and specificities approaching 100%⁶⁴ owing to the large size and limited mobility of these structures (Fig. 18-17). A notable limitation to the technique after coronary artery bypass grafting (CABG) is seen in evaluation of native CAD, in which presence of metallic clips and severe CAC leads to reduced sensitivity and

specificity, with a high rate of unevaluable coronary segments. Before reoperative CABG, cardiac CT is considered an appropriate indication, defining the relationship of sternal wires to cardiac and graft structures for the purpose of planning surgical reentry techniques. These studies require contrast-enhanced CT for opacification of grafts and the right ventricle, and a retrospective helical acquisition for cine angiographic imaging to evaluate for adherence of structures to the sternum. Patients who undergo preoperative cardiac CT angiography have improved surgical outcomes including reduced risk of perioperative MI and shorter periods of required postoperative critical care.⁶⁵ High-risk findings on cardiac CT include cardiac structures adjacent to or adherent to the sternum and coronary bypass grafts that extend into the midline⁶⁵ (Fig. 18-18). CT images also guide the surgical team on optimal locations for aortic crossclamping, to avoid regions with extensive CAC or atheroma (Fig. 18-19).

Imaging of Coronary Stents. Image artifact from metallic stents limits the application in patients with previous coronary stent procedures, inasmuch as small stents are difficult to evaluate and prone to noninterpretability. However, moderate to high accuracy (approaching 90%)⁶⁶ can be obtained with stents 3 mm or greater in diameter, with some dependence on stent design after optimization of reconstruction techniques (sharp kernel) and display characteristics (wide display window) (Fig. 18-20). Stents in the left main coronary artery may be appropriately imaged with cardiac CT angiography. Quantitative assessment of within-stent contrast density may assist in the diagnosis. A contrast density ratio of 0.81 between the stent (proximal, mid-, and distal portions) and the aorta showed a sensitivity of 90.9% and a specificity of 95.2% in-stent stenosis for stents down to 2.5 mm in size.⁶⁷ New techniques applying high-definition CT with thinner detector arrays and iterative reconstruction techniques, and using quantitative attenuation mapping, may enable more accurate detection of in-stent restenosis.⁶⁸

Avoiding Scan Artifacts. Despite optimal patient selection and preparation, scan artifacts can occur (Fig. 18-21). High heart rate (>65 beats/min for single-source scanners) can lead to coronary motion artifact, particularly within the mid-right coronary artery (Fig. 18-22). In some cases, end-systolic phases (versus diastolic phases) can resolve this issue. Newer scanners with improved temporal resolution or orthogonal x-ray sources (dual-source CT) can achieve adequate image quality at higher heart rates. Misalignment of axial image slices arises from positional changes of the heart with patient motion (particularly respiratory motion), ectopic heart beats, or abrupt changes in heart rate during scanning. Helical scan data sets generally permit editing ECG tags to delete data for ectopic beats during the scan

FIGURE 18-16 Thin cross section of coronary artery plaque as seen with standard-definition CT (detector width of 0.625 mm) (A) and high-definition CT (detector width of 0.312 mm) (B). High-definition CT may enable more accurate detection of plaque and grading of coronary stenosis but is investigational at present.

FIGURE 18-17 Cardiac CT provides high accuracy for evaluation of coronary bypass grafts owing to their large size, often limited extent of calcified atherosclerosis, and limited mobility, as shown in the oblique multiplanar reformat (A) and three-dimensional volume-rendered reformat (B). (Images courtesy Dr. Stephan Achenbach, Erlangen, Germany.)

FIGURE 18-18 High-risk substernal reoperative anatomy in a patient with previous coronary bypass surgery including a coronary bypass graft (arrow) immediately beneath the sternum, shown in axial (A) and sagittal (B) views. The right ventricle is immediately adjacent and adherent to the sternal wire (C, arrow).

FIGURE 18-19 Noncontrast CT showing extensive aortic calcification (“porcelain aorta”). **A**, In the coronal plane, calcification extends from the aortic sinotubular junction to the aortic arch. **B, C**, Cross-sectional images (at levels indicated by arrows extending from **A**) from the upper (**B**) and lower (**C**) ascending aorta show the circumferential nature of the calcification.

FIGURE 18-20 Stent imaging with cardiac CT. **A**, A large stent with uniform contrast attenuation in the lumen, indicating patency. **B**, A small stent in the left anterior descending artery with another stent in the proximal diagonal branch. Three reconstruction/display settings are shown: a medium-soft kernel, a sharp kernel, and sharp kernel reconstruction displayed with a wide window width. Visualization of in-stent restenosis in the diagonal branch is optimized with the third approach (i.e., sharp kernel, wide window display width). (Images courtesy Dr. John Lesser, Minneapolis Heart Institute, Minneapolis.)

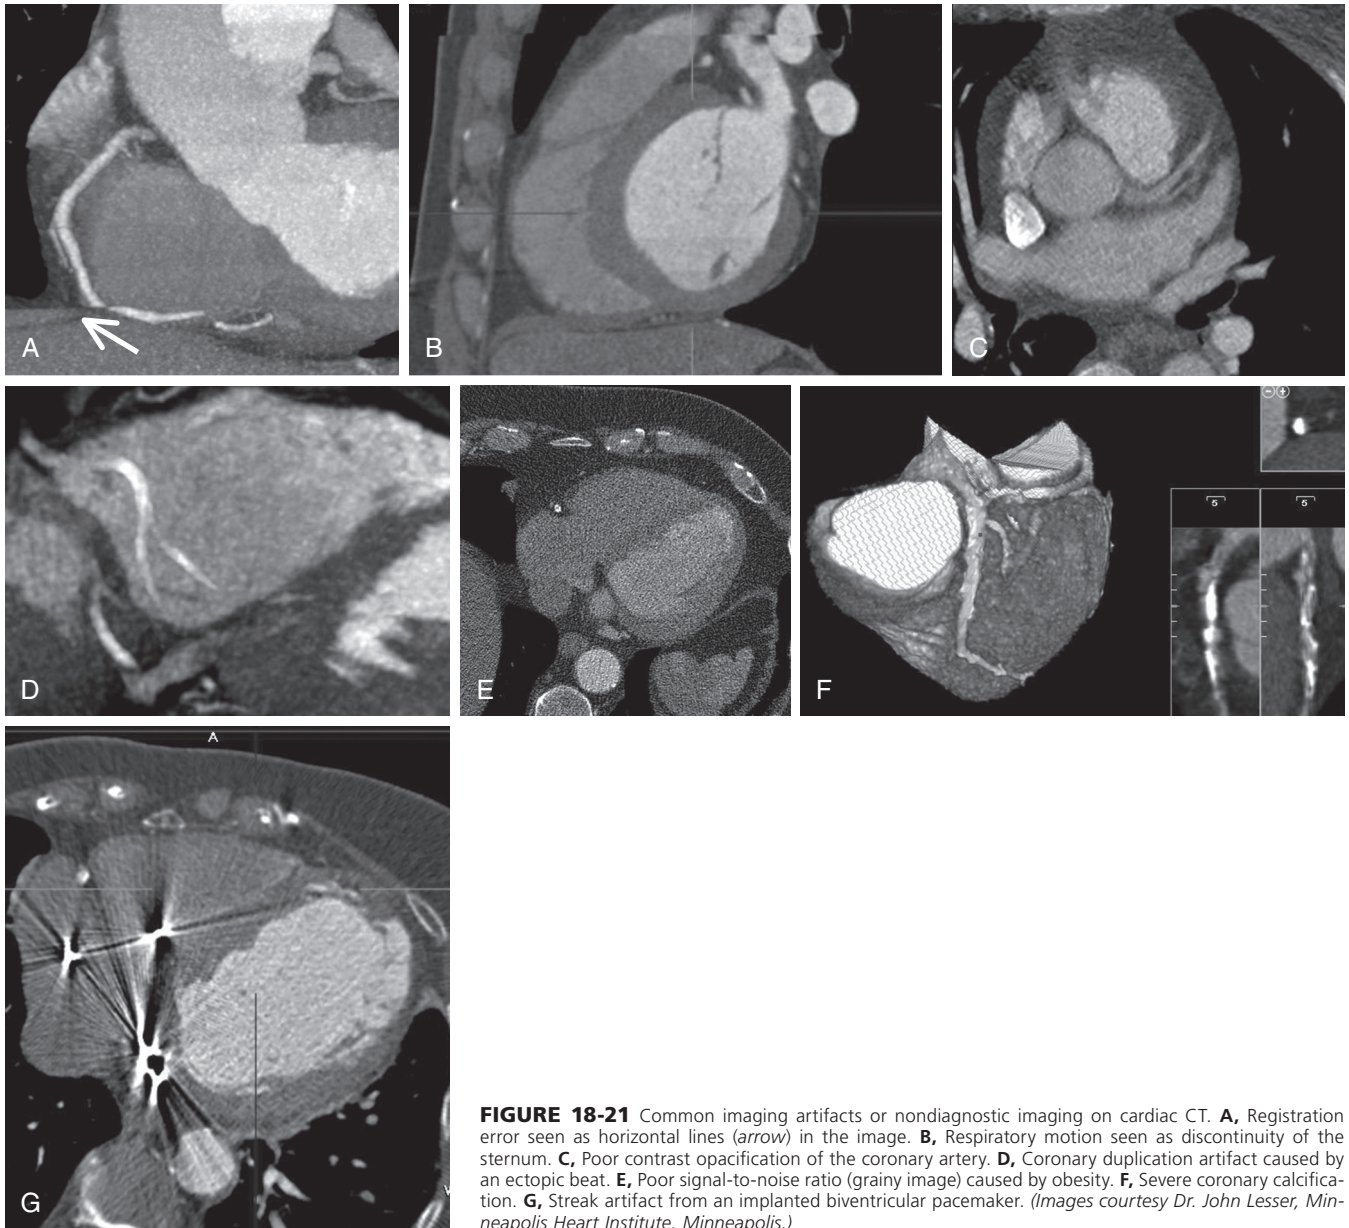

FIGURE 18-21 Common imaging artifacts or nondiagnostic imaging on cardiac CT. **A**, Registration error seen as horizontal lines (arrow) in the image. **B**, Respiratory motion seen as discontinuity of the sternum. **C**, Poor contrast opacification of the coronary artery. **D**, Coronary duplication artifact caused by an ectopic beat. **E**, Poor signal-to-noise ratio (grainy image) caused by obesity. **F**, Severe coronary calcification. **G**, Streak artifact from an implanted biventricular pacemaker. (Images courtesy Dr. John Lesser, Minneapolis Heart Institute, Minneapolis.)

FIGURE 18-22 Multiphase axial images of the right coronary artery showing motion artifact throughout the cardiac cycle including systole (0 to 40% phases) and diastole (50% to 90%). The most motion-free images of the right coronary artery (arrow) are at 40% (end-systole) and 70% (mid-diastole), when cardiac motion is minimized.

reconstruction. Highly attenuating objects (metallic objects or CAC) can produce an artifact called *beam hardening*, created by alteration in the energy spectrum of the x-ray beam. This artifact can particularly hamper interpretation of coronary plaques with highly dense calcified atherosclerosis. Finally, images with poor signal-to-noise ratio can be the result of underpenetration secondary to either scan acquisition parameters or patient body size. Thicker-slice reconstructions can improve the signal-to-noise ratio, but at the expense of spatial resolution.

Ventricular and Valvular Morphology and Function

Helical scan acquisitions, with or without tube current modulation, allow reconstruction of cardiac CT data from both systolic and diastolic phases enabling evaluation of ventricular systolic function. Such data can be displayed in cine loop format for estimation of ejection fraction and regional wall motion, or can be evaluated using quantitative segmentation software for volumetric analysis (**Fig. 18-23**). Reconstruction parameters permit thicker slice reconstructions (2 to 3 mm) with enough spatial resolution for adequate structural detail. Using such methods, determination of LV⁶⁹ and RV^{70,71} ejection fraction and volumes is highly accurate ($\pm 2\%$) compared with other methods such as cardiac magnetic resonance (CMR) (**see Chapter 17**). Myocardial morphology also can be reliably assessed for findings of previous MI such as wall thinning, calcification, or fatty myocardial replacement (indicated by negative HU densities within the myocardium). Atrial morphology and volume can also be assessed. Clot in the left atrial appendage can be identified with high negative predictive value, although delayed mixing in the setting of poor flow may result in a diagnosis of pseudothrombus. Cardiac CT

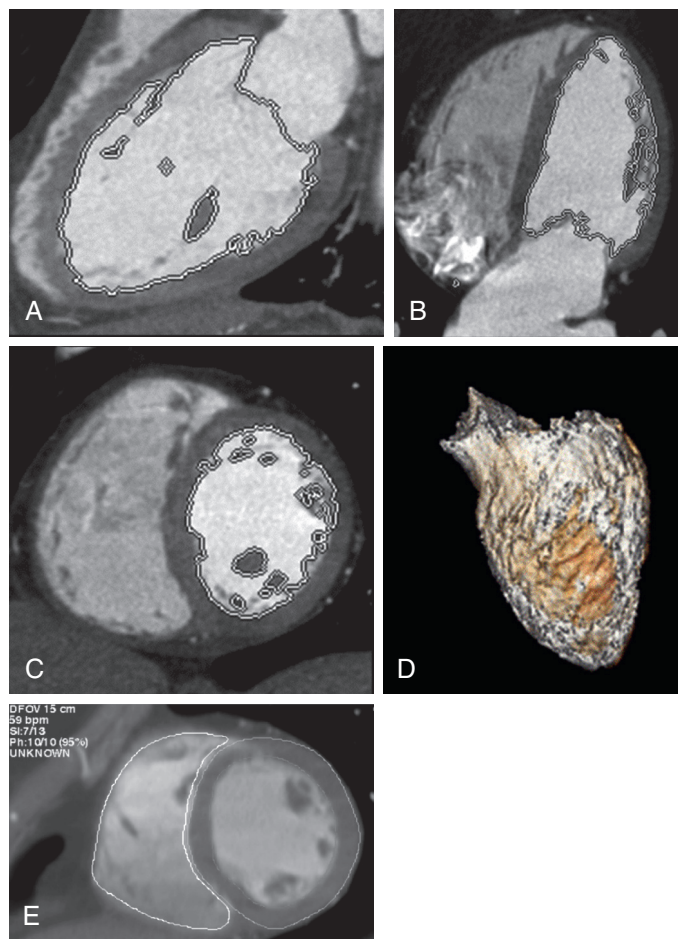

FIGURE 18-23 Ventricular segmentation in the vertical long axis (**A**), horizontal long axis (**B**), and short axis (**C**), leading to ventricular volume determination (**D**). A similar segmentation approach to the right ventricle in short axis is shown in **E**.

also provides highly accurate detection of LV mural thrombi. Mural thrombi typically have an attenuation value ranging between 25 and 80 HU (mean, approximately 40 HU) which is below that of surrounding myocardium (typically 70 to 200 HU)⁷² (**Fig. 18-24**).

Anatomic evaluation of cardiac valves and their motion also is feasible for both native⁷³ and prosthetic valves⁷⁴ (**Figs. 18-25 and 18-26**). Aortic stenosis is characterized by CT in terms of both the extent of valvular calcification and orifice area by planimetry (**see Chapter 63**).^{75,76} Aortic valvular calcification is directly related to valve area and can be quantitated using area-density methods.⁷⁷ Valve area planimetry is closely related to other invasive and non-invasive determinations in aortic stenosis. Cardiac CT performed before transcatheter aortic valve replacement (**see Chapter 56**) represents a new application of the technique described in recent guidelines from the Society of Cardiovascular CT (see **Fig. 18-26**).⁷⁸ In comparison with transesophageal echocardiography (**see Chapter 14**), cardiac CT provides a more accurate assessment of the aortic annulus area with its oblique nature, determination of optimal angiographic angulations, and detection of potential hazards such as severe aortic root calcification.

In aortic regurgitation, malcoaptation of the valve leaflets by greater than 0.75 cm² is associated with severe aortic regurgitation (**Fig. 18-27**; see also **Fig. 18-26**).⁷⁹ Prosthetic valve malfunction including size mismatch, tissue ingrowth, or valve thrombosis can be identified.^{74,80} Increasingly, cardiac CT imaging in patients with prosthetic valve endocarditis identifies paravalvular leaks (see **Fig. 64-4**), and can provide a preoperative coronary arteriographic assessment when cardiac surgery is anticipated. The weakness of cardiac CT for evaluation of valve disorders is the inability to assess hemodynamics, so complementary imaging should include Doppler echocardiography.

Cardiac CT depicts the structural characteristics of congenital heart disease (**see Chapter 62**) and coronary artery anomalies, particularly as an alternative to CMR in patients with implanted pacemakers. However, concerns over radiation exposure in young persons warrant strict attention to scan acquisition parameters, including the use of 80 kVp imaging to limit radiation exposure.

Acute Aortic Syndromes and Pulmonary Embolism

Multidetector CT provides accurate diagnosis of other serious causes of acute chest pain or ischemic equivalent symptoms including acute

FIGURE 18-24 Contrast-enhanced cardiac CT showing a mural thrombus, attenuation value 35 HU, in the distal apical septum, displayed in a four-chamber view.

FIGURE 18-25 Valvular heart disease on cardiac CT. **A**, Aortic stenosis is characterized by restricted motion of calcified valve leaflets in systole. Planimetry of the aortic valve area showed severe aortic stenosis, with an area of 1 cm^2 . **B**, Malcoaptation of the aortic valve leaflets in diastole with an area of 0.8 cm^2 , consistent with severe aortic regurgitation. **C**, Bileaflet prosthetic mitral valve with a stuck leaflet secondary to subacute valve thrombosis (arrow).

FIGURE 18-26 Contrast-enhanced cardiac CT showing the typical appearance of transcatheter aortic valve replacement shown before (**A**) and after deployment, with short-axis imaging of the expanded metal stent within the aortic annulus (**B**), and long-axis imaging (**C**) showing the relationship of the prosthesis to the left main coronary artery. (From Achenbach S, Delgado V, Hausleiter J, et al: SCCT expert consensus document on computed tomography imaging before transcatheter aortic valve implantation (TAVI)/transcatheter aortic valve replacement (TAVR). *J Cardiovasc Comput Tomogr* 6:366, 2012.)

FIGURE 18-27 Aortic valve endocarditis with Gerbode defect. **A**, The aortic valve shows a low-attenuation object (arrow) attached to the valve, along with aortic root enlargement, and severe aortic regurgitation with malcoaptation of the valve leaflets in diastole (**B**). A ventriculoatrial septal defect (Gerbode defect) as a complication of endocarditis is seen in **C** (arrow).

aortic syndromes (aortic dissection) (**Fig. 18-28A**), and aortic intramural hematoma (**Fig. 18-28B**) and pulmonary embolism (**Fig. 18-28C**). Helical CT has a sensitivity of 100% and a specificity of 98% for the diagnosis of aortic dissection among patients with low pretest likelihood of dissection.⁸¹ Similarly, accuracy for the diagnosis of pulmonary embolism using multidetector CT is high, with a negative predictive value of 99% among patients with low to moderate pretest

likelihood, although accuracy for the detection of subsegmental pulmonary emboli may be limited.⁸² In spite of the accuracy of dedicated multidetector CT for these conditions and the general recommendation that such noncardiac incidental abnormalities should be detected on cardiac CT, the routine adaptation of cardiac CT protocols (such as in the “triple rule-out protocol”) for optimal detection of such noncoronary diagnoses is complicated and presently not

FIGURE 18-28 **A**, Dissection of the descending aorta (white arrow) in a patient with previous ascending aorta dissection repair (black arrow). Graft material surrounds the aortic root. First-pass contrast attenuation is seen in the true lumen of the descending aorta. **B**, Aortic intramural hematoma, seen as low-attenuation material in the wall of the ascending and descending segments of the aorta (upper and lower arrows). **C**, Pulmonary embolism (white arrow) in the left lower pulmonary artery, seen as an area of hypoattenuation (clot). Multiple, bilateral pulmonary emboli were present, leading to delayed contrast transit, manifested as greater contrast attenuation in the pulmonary artery (black arrow) and aorta.

FIGURE 18-29 Stress CT myocardial perfusion imaging using adenosine. CT perfusion images including polar maps at rest (left) and during stress (right) disclose a reversible posterolateral perfusion defect (arrows) on the stress images. (From George RT, Arbab-Zadeh A, Miller JM, et al: Computed tomography myocardial perfusion imaging with 320-row detector computed tomography accurately detects myocardial ischemia in patients with obstructive coronary artery disease. *Circ Cardiovasc Imaging* 5:333, 2012.)

recommended. Longer scan range increases radiation exposure, emphasizing the need for radiation reduction techniques, and increases the potential for incidental scan findings. In general, the thin-slice collimation that is needed for coronary evaluations is not needed for aortic or pulmonary artery evaluations, but ECG gating is necessary to avoid aortic motion artifact mimicking aortic dissection. Contrast volume and timing are crucial factors in providing optimal contrast enhancement of all three (pulmonary, coronary, and aortic) vasculatures. Finally, differing pretest probabilities for aortic or pulmonary artery pathology will impact the negative and positive predictive value in that sensitivity and specificity of the technique is imperfect.

Coronary Blood Flow, Physiology, and Myocardial Scar

Myocardial attenuation reflects relative coronary blood flow on first-pass imaging. On this basis and founded on the relationship between myocardial flow reserve and arterial stenosis, first-pass CT stress perfusion imaging is being developed. The imaging protocol (Fig. 18-29) includes contrast-enhanced CT angiography both at rest and during the administration of adenosine agonists.⁸³ Several studies have reported the feasibility and accuracy of this approach, most commonly

using 320-slice CT or 128-slice dual-source CT. The sensitivity for the detection of significant coronary stenosis ranges from 72% to 98%, with specificity ranging from 71% to 92%, with radiation doses as low as 2.5 mSv using high-pitch helical CT.⁸⁴ A meta-analysis found an overall pooled sensitivity of 81% and specificity of 93% for this method.⁸⁵ The primary limitation of this technique is the radiation exposure, but current wide-area scanners or high-pitch helical acquisitions, coupled with other dose-sparing techniques, now enable CT stress perfusion imaging with a radiation exposure at or significantly beneath that of nuclear myocardial perfusion imaging.

Another newer technique is the application of computational FFR (see Chapters 49 and 54) from resting coronary CT angiographic images. Measured from standard first-pass coronary CT angiography (Fig. 18-30), its accuracy has been compared with that for invasive measurement of FFR of 0.80 or less. In a multicenter trial in 252 patients, overall accuracy was limited at 73%, with sensitivity of 90% and specificity of 54%.⁸⁶ The technique, still in development, currently requires off-site analysis but has the potential advantage of assessment from routine coronary CT angiograms acquired with the patient at rest.

Detection of myocardial scar and viability is a relevant measurement in patients with known cardiovascular disease. Cardiac CT detects

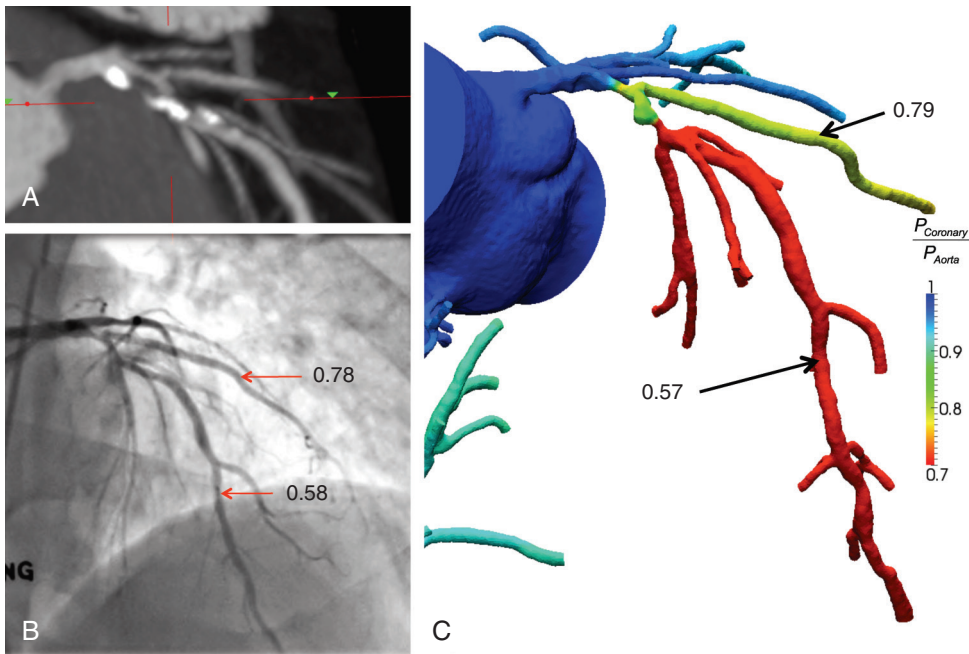

FIGURE 18-30 CT fractional flow reserve (FFR) using computational fluid dynamics. From the invasive coronary angiogram (A), coronary lesions assessed by invasive FFR (B) are correlated with CT-derived FFR (C). (From Nakazato R, Park HB, Berman DS, et al: Non-invasive fractional flow reserve derived from CT angiography (FFRCT) for coronary lesions of intermediate stenosis severity: Results from the DeFACTO study. *Circ Cardiovasc Imaging* 6:881, 2013.)

comparable infarct sizing based on late enhancement imaging.⁸⁸ Late myocardial enhancement imaging involves specific cardiac CT acquisition with both infusion of additional contrast medium and a delay of approximately 10 minutes. The kinetics of iodinated contrast are similar to those for gadolinium, with accumulation within the interstitial space of fibrotic myocardium. Under delayed imaging, contrast preferentially accumulates within areas of scarring and can be detected on delayed imaging⁸⁹ (Fig. e18-4). This imaging can be accomplished with lower radiation exposure than with first-pass cardiac CT by imaging with wider collimation, axial scanning, and lower tube output and tube voltage. Optimal imaging protocols, however, are not yet established. Display characteristics favoring the detection of myocardial scar include the use of a narrow window width (200) and lower display center (100) and use of minimum-intensity projection. Delayed enhancement on cardiac CT indicates regions of myocardium with reduced likelihood of functional recovery and identifies patients whose ejection fraction will remain depressed after MI, particularly when a transmural pattern of delayed enhancement is present.⁹⁰

FIGURE 18-31 The spectrum of chronic MI as seen on cardiac CT. A, Thinning of myocardium subsequent to anteroseptal MI (arrow). B, Hypoattenuation (HU < 0) of the ventricular septum indicative of chronic MI and fibrofatty change (arrow). C, Calcification of the LV apex (arrow). D, Delayed enhancement imaging (at 10 minutes) showing late enhancement of the anteroapex, indicative of chronic scarring and nonviable myocardium.

regions of myocardial hypoattenuation on first-pass imaging, which when noted with myocardial thickness less than 5 mm suggests previous MI and nonviable myocardium (Fig. 18-31). Such first-pass defects typically have a level of myocardial attenuation less than 50% of the surrounding myocardium; this may even be zero in the setting of fibrofatty myocyte replacement from chronic MI, although a zero value also can be present in normal persons.⁸⁷ Infarct size on cardiac CT correlates closely with that obtained on CMR (see Chapter 17), with slight underestimation of infarct size on first-pass imaging and

INCIDENTAL SCAN FINDINGS

Incidental scan findings during cardiac CT span a broad spectrum from noncardiac vascular (aorta, pulmonary artery, and pulmonary veins), pulmonary, mediastinal, musculoskeletal, soft tissue, and gastrointestinal structures. In a series of subjects studied with multidetector CT, incidental scan findings were common (40% to 50%). Although most patients do not require further evaluation, a minority (5% to 10%) will require second imaging tests or clinical follow-up. Guidelines for follow-up of pulmonary nodules include no subsequent investigation of small (<4 mm) nodules (Table e18-3), although larger nodules require further evaluation.⁹¹ Despite the absence of data showing an overall improvement in outcomes or management, present practice requires the evaluation of incidental scan findings using full field-of-view reconstructions by cardiovascular imagers with expertise in evaluation of other thoracic pathologic features.⁹²

TRAINING AND CERTIFICATION

Cardiac CT represents a new imaging modality for many cardiovascular specialists. Competency⁹³ and training⁹² standards for cardiac CT have been published for cardiovascular specialists, who require a broad knowledge base in CT methods and case experience from a minimum of 150 cardiac CT angiography cases, which can be obtained from both live (50 cases) and workstation review experience. Professional certification is governed by the Certification Board in Cardiovascular Computed Tomography⁹⁴ of the Council for Certification in Cardiovascular Imaging, and CT laboratory accreditation by the Intersocietal Commission for the Accreditation of Computed Tomography Laboratories or the American College of Radiology.

TABLE e18-3 Recommendations for Follow-up and Management of Nodules <8 mm Detected Incidentally at Nonscreening Computed Tomography

NODULE SIZE (MM)	RECOMMENDATIONS	
	Low-Risk Patient	High-Risk Patient
≤4	No follow-up needed [§]	Follow-up CT at 12 months; if findings unchanged, no further follow-up needed [¶]
>4–6	Follow-up CT at 12 months; if unchanged, no further follow-up [¶]	Initial follow-up CT at 6–12 months, then at 18–24 months if no change [¶]
>6–8	Initial follow-up CT at 6–12 months, then at 18–24 months if no change	Initial follow-up CT at 3–6 months, then at 9–12 and 24 months if no change
>8	Follow-up CT at around 3, 9, and 24 months; dynamic contrast-enhanced CT, PET, and/or biopsy	Same as for low-risk patient

Note: Newly detected indeterminate nodule in persons 35 years of age or older.

*Average of length and width.

[†]No history of smoking (or minimal smoking) and of other known risk factors.

[‡]History of smoking or of other known risk factors.

[§]The risk of malignancy in this category (<1%) is substantially less than that with a baseline CT scan for an asymptomatic smoker.

[¶]Nonsolid (ground-glass appearance) or partly solid nodules may require longer follow-up to exclude indolent adenocarcinoma.

APPROPRIATE USE CRITERIA

Cardiac Computed Tomography

Allen J. Taylor

Appropriate use criteria (AUC) for cardiac CT were first developed in 2006¹ by the American College of Cardiology in a joint society effort. Rapid evolution in CT technology and the data on its clinical application led to an update in the AUC in 2010 (**Table 18G-1**).² The AUC are developed by means of a regimented process from the modified Delphi exercise of the Rand methodology. They adhere to the conceptual application of pretest risk or probability determination before diagnostic testing. An appropriate imaging test is defined as one in which the value of the expected incremental information, combined with clinical judgment, exceeds the expected negative consequences by a sufficiently wide margin for a specific indication that the procedure is generally considered to represent acceptable care and to constitute a reasonable approach for the indication. Negative consequences include the risks associated with the procedure (radiation or contrast exposure) and the downstream impact of poor test performance, such as delay in diagnosis (false negatives) or inappropriate diagnosis (false positives). Cardiac CT is performed in accordance with best practice standards as delineated in the imaging guidelines of the Society of Cardiovascular Computed Tomography^{3,4} by competent and appropriately credentialed physicians. These standards include optimization of the scan protocol to limit radiation exposure. In addition, the criteria assume specific technical factors, including the following:

1. Cardiac CT imaging equipment is available that has the minimal technical capabilities required for the indication. Typical technical parameters for studies performed on multidetector-row scanners

include CT equipment enabling 64 or more slices, submillimeter spatial resolution, and gantry rotation time no greater than 420 milliseconds. Appropriate computer software must be available for image analysis.

2. Patients are optimal candidates for cardiac CT under the following conditions:
 - Regular heart rate and rhythm including a heart rate at a level commensurate with the temporal resolution of the available scanner
 - Body mass index below 40 kg/m²
 - Normal renal function
3. For CT angiography, patient requirements may include the ability to hold still and to follow breathing instructions, to tolerate beta blockers, to tolerate sublingual nitroglycerin, and to lift both arms above the shoulders.
4. All indications for cardiac CT were considered with the following important assumptions:
 - All indications should first be evaluated on the basis of the available medical literature.
 - In many cases, studies published in the medical literature are reflections of the capabilities and limitations of the test but provide minimal information about the role of the test in clinical decision making.
 - AUC development requires determination of a reasonable course of action for clinical decision making based on a risk-to-benefit tradeoff as determined by individual patient indications.
5. For all stress imaging referenced in the indications, the mode of stress testing was assumed to be exercise for patients able to exercise. For patients unable to exercise, pharmacologic stress testing was assumed to be used.

These criteria were developed for consideration both in the delivery of these services and in the relevant policy positions, including reimbursement. By contrast, services performed for inappropriate indications are likely to require additional documentation to justify reimbursement because of the unique circumstances or clinical

92. Noninvasive coronary vein mapping before placement of biventricular pacemaker		A
93. Localization of coronary bypass grafts and other retrosternal anatomy before reoperative chest or cardiac surgery		A

METs = estimated metabolic equivalents [of exercise]; PCI = percutaneous coronary intervention.

Modified from Taylor AJ, Cerqueira M, Hodgson J, et al: ACCF/SCCT/ACR/AHA/ASE/ASNC/SCMR 2010 appropriate use criteria for cardiac computed tomography. *J Am Coll Cardiol* 56:1864, 2010.

profile for such a patient. Uncertain ratings are those for which expert opinion or the available data vary or are rapidly evolving. These criteria are intended to provide a practical guide and perspective to clinicians and patients in considering cardiac CT imaging and to promote more appropriate test use, including avoidance of underuse or overuse.

- A total of 31 indications were carried forward from the 2006 document, including previous ratings of appropriate (10 indications), uncertain (10), or inappropriate (11). Among these, 8 shifted up one category from either uncertain to appropriate or from inappropriate to uncertain. The other 23 indications had unchanged appropriateness ratings.
- One area of expansion from the 2006 criteria involved symptomatic patients without known heart disease. Cardiac CT is thought to be appropriate primarily for situations involving a low or intermediate pretest probability of CAD. Scenarios involving patients with a high probability of CAD are rated as uncertain with the exception of a patient with an interpretable electrocardiogram who is able to exercise and for definite MI.
- Non-contrast-enhanced CT calcium scoring is judged appropriate for patients at intermediate CHD risk and for the specific subset of low-risk patients in whom a family history of premature CHD is present. Intermediate risk is defined as a 10-year risk of between 10% and 20%, although individual exceptions to a broadened intermediate risk range of 6% to 20% are recognized for certain patient subsets with generally low absolute risk but high relative risk (younger men and women). Screening of asymptomatic patients by coronary CT angiography is considered inappropriate, as is repeated coronary calcium testing. Repeated CT angiography in asymptomatic patients or patients with stable symptoms with previous test results is broadly considered inappropriate.
- Within the general category of heart failure, CT angiography is appropriate with reduced LV ejection fraction with low or intermediate pretest CAD probability.
- As part of the preoperative evaluation, CT angiography is viewed as a potential option among patients undergoing heart surgery for noncoronary indications (e.g., valve replacement surgery or atrial septal defect closure) when the pretest CAD risk is either intermediate (appropriate) or low (uncertain). By comparison, no appropriate indications for coronary CT angiography as part of the preoperative evaluation for noncardiac surgery are recognized.
- The evaluation of coronary stents is considered as a function of patient symptom status, time from revascularization, and stent size. Only with larger stents (≥ 3 mm in diameter) after long time periods (≥ 2 years) is stent imaging considered uncertain, and only with left main stents is imaging of stents considered appropriate.
- A strength of cardiac CT imaging is the capability for evaluation of cardiac structure and function. Appropriate indications include

coronary anomalies, congenital heart disease, evaluation of RV function, evaluation of LV ejection fraction when images from other techniques are inadequate, and evaluation of prosthetic heart valves. New to this document is the use of cardiac CT for evaluation of myocardial viability when other modalities are inadequate or contraindicated (uncertain) and in suspected arrhythmogenic RV dysplasia (appropriate).

- The use of cardiac CT is appropriate before electrophysiologic procedures for anatomic mapping or before repeated sternotomy in reoperative cardiac surgery.

The current AUC methodology⁵ has changed the nomenclature such that ratings of 1 to 3 are now termed “rarely appropriate,” instead of “inappropriate,” and ratings of 4 to 6 are now termed “may be appropriate.” Ratings of 7 to 9 remain “appropriate.” However, the AUC for cardiac CT² have not yet been updated to reflect this change in terminology. The recent AUC documents for multimodality imaging in stable ischemic heart disease and heart failure^{6,7} do conform to the updated terminology and provide criteria for use of CT in these conditions relative to the applications of the other imaging modalities (see Guidelines: Multimodality Imaging in [Chapter 20](#)).

INDICATIONS FOR DIAGNOSTIC CARDIAC CATHETERIZATION

The decision to recommend cardiac catheterization is based on an appropriate risk-benefit ratio. In general, diagnostic cardiac catheterization is recommended whenever it is clinically important to define the presence or severity of a suspected cardiac lesion that cannot be evaluated adequately by noninvasive techniques. Because the risk for a major complication from cardiac catheterization is less than 0.5% and mortality is less than 0.08%, there are few patients who cannot undergo the procedure safely in an active laboratory. Intracardiac pressure measurements and coronary arteriography are procedures that can be performed best with reproducible accuracy by invasive catheterization. Alternatively, intracardiac pressures can be estimated noninvasively with echocardiography (see Chapter 14). Coronary computed tomography (CT) angiography can also be used for assessment of coronary anatomy (see Chapter 18) and provides adjunctive information on plaque distribution and composition. However, limitations of spatial resolution, heart rate variability, patient cooperation, and radiation dosing limit the ability of CT to replace cardiac catheterization for definition of coronary artery stenosis.

To understand the various indications for diagnostic cardiac catheterization, integration of knowledge from multiple American College of Cardiology/American Heart Association (ACC/AHA) guidelines is necessary.¹⁻⁹ These guidelines address specific indications for cardiac catheterization related to disease states, including guidelines for the management of patients with valvular heart disease,¹ chronic heart failure,² ST-elevation myocardial infarction (STEMI),³ percutaneous coronary intervention (PCI)⁴ and coronary artery bypass grafting (CABG),⁵ unstable angina or non-STEMI,⁶ and congenital heart disease.⁷

Cardiac catheterization is indicated in diverse populations. At one extreme, many critically ill and hemodynamically unstable patients are evaluated during acute coronary syndromes, severe heart failure, or cardiogenic shock. At the other end of the spectrum, many procedures are performed in an outpatient setting. Such settings include hospitals with or without cardiac surgical capability and freestanding or mobile laboratories.⁹

Cardiac catheterization should be considered a diagnostic study used in combination with complementary noninvasive tests. For example, cardiac catheterization in patients with valvular or congenital heart disease is best performed with full prior knowledge of any noninvasive imaging and functional information. This allows catheterization to be directed and simplified without obtaining

redundant anatomic information that is reliably available with echocardiography, cardiac magnetic resonance (CMR) (see Chapter 17), or CT.

Identification of coronary artery disease and assessment of its extent and severity are the most common indications for cardiac catheterization in adults. The information obtained is crucial to optimize selection of mechanical or medical therapy. In addition, dynamic coronary vascular lesions, such as spasm, myocardial bridging, and plaque rupture with thrombosis, can be identified. The consequences of coronary heart disease, such as ischemic mitral regurgitation and left ventricular (LV) dysfunction, can also be defined. During PCI for acute coronary syndromes, patients are studied during evolving acute myocardial infarction, with unstable angina, or in the early period after acute myocardial injury. The optimal timing for catheterization and revascularization has been described in various guidelines^{3,4,6} (see Chapters 52 and 53).

In patients with myocardial disease and LV dysfunction, cardiac catheterization provides important hemodynamic and coronary artery information. It can be used to evaluate the severity of coronary artery disease and quantify LV and right ventricular (RV) hemodynamics and function. In patients with angina and impaired LV function, noninvasive testing has limitations and coronary angiography is often indicated to differentiate ischemic from nonischemic cardiomyopathy.² Cardiac catheterization also permits quantification of the severity of both diastolic and systolic dysfunction and differentiation of myocardial restriction from pericardial constriction.

In patients with valvular heart disease, cardiac catheterization is both confirmatory of and complementary to findings on echocardiography and CMR (see Chapter 63). Cardiac catheterization can define the severity of valvular stenosis or regurgitation, particularly when noninvasive studies are inconclusive or the results are disparate from the clinical findings. Knowledge of coronary artery anatomy is necessary in most adults older than 35 years when valve surgery is planned.¹ However, catheterization may be unnecessary in some preoperative situations, such as younger patients (<55 years) with atrial myxoma, endocarditis, or acute valvular regurgitation. Identification of congenital anomalies, quantification of the hemodynamic consequences of valvular lesions (such as pulmonary hypertension), and the acute hemodynamic response to pharmacologic therapy can provide useful preoperative information that helps define the risk and response to surgery and permits a more directed surgical approach.¹

The current role of cardiac catheterization in certain congenital disease states has been addressed in guidelines for adults with congenital heart disease⁷ (see Chapter 62). Echocardiography with

TABLE 19-1 Relative Contraindications to Diagnostic Cardiac Catheterization

Acute gastrointestinal bleeding
Severe hypokalemia
Uncorrected digoxin toxicity
Anticoagulation with INR >1.8 or severe coagulopathy
Previous anaphylactoid reaction to contrast media
Acute stroke
Acute renal failure or severe chronic non-dialysis-dependent kidney disease
Unexplained fever or untreated active infection
Severe anemia
Uncooperative patient

Doppler and CMR often provide adequate information. Because gross cardiac anatomy can generally be well defined by these methods, catheterization is required only if certain hemodynamic information (e.g., quantification of shunt severity, pulmonary vascular resistance [PVR], and reversibility of pulmonary arterial hypertension with a vasodilator) is needed for confirmation in determining the indications for surgical procedures or if percutaneous interventions are being considered.

There is no true absolute contraindication to cardiac catheterization other than refusal by a competent patient. The procedure can be performed successfully with relatively low risk even in the most critically ill patients. Relative contraindications to cardiac catheterization are summarized in [Table 19-1](#).

TECHNICAL ASPECTS OF CARDIAC CATHETERIZATION

Catheterization Laboratory Facilities

Cardiac catheterization facilities have several venues, including traditional hospital-based laboratories with in-house cardiothoracic surgical programs, hospital-based laboratories without on-site surgical programs, freestanding laboratories, and mobile laboratories. Of the 5099 hospitals in the United States, 4345 (85%) now have cardiac catheterization laboratories and 1061 (21%) provide cardiac surgical services. At present, approximately 75% of cardiac catheterization laboratories have on-site surgical backup. According to a recent joint position paper,⁹ a cardiac catheterization laboratory with surgical on-site support services allows cardiac catheterization to be performed safely on any patient with heart disease. A hospital with all these services is considered a “full-service” facility. Cardiac surgical capability, as well as other ancillary services, including cardiac anesthesia, is a critical service. With such support a hospital is fully equipped for complex studies and interventions. Although direct surgical intervention is infrequently necessary, such expertise, including equipment, personnel, cardiac anesthesiologists, perfusionists, and cardiac and vascular surgeons, helps support high-risk patients and management of the complications that can arise. High-risk diagnostic studies and all elective percutaneous interventions should be performed in laboratories with on-site surgical facilities. Recommended on-site support services for a full-service facility include cardiac surgery, cardiac anesthesia, critical care unit, vascular services, hematologic consultative and blood bank services, advanced imaging services (echocardiography/Doppler, CMR, CT), mechanical circulatory support services, and endovascular surgery/interventions.⁹

The goal of freestanding and mobile cardiac catheterization facilities is to reduce cost while offering services in a convenient location for low-risk patients. The safety of mobile catheterization in properly selected low-risk patients appears to be comparable to that in other settings.

As a result of the documented safety and cost-effectiveness of diagnostic cardiac catheterization in the outpatient setting, approximately 50% of hospital-based procedures are currently performed on an outpatient basis. In general, patients who require preprocedural hospitalization for diagnostic catheterization are uncommon. Such patients include those with severe congestive heart failure and those with stage 4 chronic kidney disease requiring additional prehydration. The need for hospitalization to bridge patients in switching from warfarin to heparin has been obviated mainly by the use of low-

molecular-weight heparin as an outpatient strategy for anticoagulation, except for patients with mechanical heart valves.¹

Noninvasive testing can identify patients who would be more appropriately evaluated in a setting in which cardiac surgery is available, including those with severe ischemia discovered during stress testing, ischemia at rest, highly suspected severe left main or proximal three-vessel disease, critical aortic stenosis, and severe comorbid disease. Most patients can be discharged on the same day within 2 to 6 hours after the procedure.

The most common reason for postprocedural hospitalization is hematomas, which necessitate additional bed rest and observation. In addition, diagnostic findings from the procedure may require hospitalization, including severe left main or three-vessel disease. Other potential indications for postprocedure hospitalization include decompensated heart failure, unstable ischemic symptoms, severe aortic stenosis with LV dysfunction, renal insufficiency requiring further hydration, and need for continuous anticoagulation.

The hybrid cardiac catheterization laboratory has recently gained popularity with the advent of transcatheter valvular and structural heart interventions. Also, combined valvular or coronary artery surgery with PCI is well suited for hybrid suites. The main impetus is to provide high-resolution imaging with the sterility and capabilities of a cardiovascular surgical operating room. Lighting and air exchange must conform to operating room standards. Space requirements are generally larger than those needed for standard operating room or catheterization laboratories to accommodate the multidisciplinary team and equipment. These facilities can be located either in the cardiac catheterization laboratory or in the operating room. Dedicated catheter laboratory and/or operating room personnel are critical to ensure consistent high-quality outcomes after these complex procedures.

Laboratory Procedural Volume. For proficiency to be maintained, laboratories for adults should perform a minimum of 300 procedures per year. According to the Accreditation Council for Graduate Medical Education guidelines for diagnostic catheterization, physicians in training must spend a total of 8 months and perform more than 300 cases, including more than 200 as a primary operator, to be credentialed for level II diagnostic cardiac catheterization procedures in practice.⁸ However, the minimum volume for practicing physicians has not been established.⁹ Regular evaluation with quality assessment of laboratory, physician, nurse, and technologist performance and outcomes is mandatory. The laboratory director should have at least 5 years of catheterization experience. In a laboratory performing PCI, the director should be board-certified in interventional cardiology. The director is responsible for credentialing of physicians; review of laboratory, physician, and ancillary personnel performance; and provision of necessary training.

Equipment. Equipment for cardiac catheterization includes the radiographic system and physiologic data monitoring, sterile supplies, imaging for vascular access, and an emergency cart and defibrillator. Also necessary is support equipment consisting of a power injector, image processing with digital archiving, viewing stations, and a uniform method of report generation that allows data analysis of outcomes and procedural technique.

Radiographic Equipment. High-resolution x-ray imaging is required for optimal performance of catheterization procedures. The equipment needed includes a generator, x-ray tube, flat panel detector, expansive modulation, video image capture, image display, and digital archiving.¹⁰ The flat panel detector produces a direct digital video signal from the original visible light fluorescence without the intermediate visible light stage.

Immediate review, quantitative computer analysis, image manipulation, road maps, and flicker-free images at low frame rates minimize exposure of patients and personnel to radiation. Transfer of images between laboratories, hospital networks, and physician offices is accomplished with the use of remote secure Internet access. The development of digital imaging and communication standards for cardiac angiography has allowed compatibility among different vendors.

Physiologic Monitors. Continuous monitoring of blood pressure and the electrocardiogram (ECG) is required during cardiac catheterization. Systemic, pulmonary, and intracardiac pressure is generally recorded with use of fluid-filled catheters connected to strain gauge pressure transducers and then transmitted to a monitor. Equipment for determination of thermodilution cardiac output and blood gas determination, as well as a standard 12-lead ECG, is necessary. Measurement of oxygen consumption for determination of cardiac output with the Fick method should be available in laboratories performing valvular and congenital diagnostic procedures.

Radiation Safety. The main guiding principle of x-ray exposure is ALARA (as low as reasonably achievable). This implies that no level of radiation is completely safe to patients or providers. The effects of radiation can be classified as either deterministic or stochastic. Both are characterized by a delay between radiation and effect. The delay may be hours to years. Examples of deterministic effects include skin erythema, desquamation, cataracts, hair loss, and skin necrosis. Skin injury is the most common deterministic effect from radiation. Early transient erythema can develop within hours, but most skin injuries do not appear for 2 to 3 weeks after exposure. Stochastic effects are related to probability and are not proportional to dose, although the likelihood of an effect is related to dose. Examples of this effect include neoplasms and genetic defects. The dose-area product is the absorbed dose to air (air kerma) multiplied by the cross-sectional area of the x-ray beam at the point of measurement. It is an approximation of the total x-ray energy delivered to the patient and is a measure of the patient's risk for stochastic effects.¹⁰

Deterministic effects are dose related, which means that below a certain dose, there is no effect. However, when a threshold is exceeded, severity increases with dose. The estimated dose range for cardiac catheterization is 1 to 10 millisievert (mSv), which is the equivalent of 2 to 3 years of natural background radiation. The typical dose is 3 to 5 mSv.¹⁰ Another measure of skin dose is the interventional reference point, which is located 15 cm from the isocenter of the x-ray tube and is an estimation of the skin entrance point of the beam.

The basic principles of minimizing radiation exposure include minimizing fluoroscopic beam time for fluoroscopy, using beam collimation, positioning the x-ray source and image reception optimally, using the least magnification possible, rotating the radiographic projection during long procedures to minimize exposure of skin at the entrance port, and recording the estimated patient dose.

For laboratory personnel, the most important factors are maximizing distance from the source of x-rays and using appropriate shielding, including lead aprons, thyroid collars, lead eyeglasses, and movable leaded barriers. Severely angulated views, particularly the left anterior oblique (LAO) view, substantially increase the radiation exposure of operators because of scatter from patients.

A method of measuring radiation exposure of personnel is required. It is recommended that at least two film badges be worn. One should be worn on the outside of the apron at the neck and another under the apron at the waist. The latter monitors the effectiveness of the lead apron. The maximum allowable whole-body radiation dose per year for those working with radiation is 5 roentgen-equivalents-man (rem = 50 mSv), or a maximum of 50 rem in a lifetime.¹⁰

Catheterization Laboratory Protocol

Preparation of the Patient for Cardiac Catheterization

Before arrival in the catheterization laboratory, the cardiologist responsible for the procedure should explain the procedure fully, including the risks and benefits, and answer questions from the patient and family. Precatheterization evaluation includes a patient history, physical examination, and ECG. Routine laboratory studies include a complete blood count with platelets, serum electrolyte determinations with creatinine and estimated glomerular filtration rate (eGFR), prothrombin time with international normalized ratio (INR) (in patients receiving warfarin or with hepatic disease), and the partial thromboplastin time (in patients receiving heparin). Important components of the history that need to be addressed include diabetes mellitus (insulin or non-insulin requiring), kidney disease, anticoagulation status, peripheral arterial disease, and previous allergy to contrast media or latex. Full knowledge of any previous procedures, including cardiac catheterizations, PCI, peripheral arterial interventions or surgery, and cardiac surgery, is necessary.

Patients should be fasting for at least 6 hours, and an intravenous line should be established. Oral or intravenous sedation is often administered (e.g., benzodiazepine). Pulse oximetry should be used to monitor respiratory status. Warfarin should be discontinued approximately 3 days before and the INR should be less than 1.8 to minimize risk for bleeding. An INR lower than 2.2 is acceptable for radial artery access.⁹ In patients receiving dabigatran, use of the medication should be discontinued 24 hours before catheterization in patients with normal renal function and 48 hours before in those with an eGFR higher than 30 and lower than 50 mL/min. A lower

eGFR will require several days of cessation. Aspirin and/or other oral antiplatelet agents are continued before the procedure. Patients with diabetes receiving metformin should have use of the medication discontinued the morning of the procedure and not be restarted until renal function is stable for at least 48 hours after the procedure.¹¹ To minimize the risk for contrast-induced nephropathy, all patients should receive hydration before and after the procedure. The amount of hydration is dependent on LV function and baseline fluid status. However, if tolerated, a total of 1 liter of normal saline administered between initiation and completion of the procedure is recommended. Another hydration regimen that has been studied to prevent contrast-induced nephropathy in patients with chronic kidney disease is the use of sodium bicarbonate at 3 mL/kg for 1 hour before the procedure and 1 mL/kg for 6 hours after.¹² This regimen was initially reported to be superior to normal saline, but recent data have shown equivalence. Despite this lack of superiority, it is a simple and rapid regimen for prevention of contrast-induced nephropathy.

Those with a previous history of allergy to contrast media need prophylaxis before the procedure.¹³ A recommended regimen is the administration of either prednisone (50 mg by mouth) or hydrocortisone (100 mg by intravenous push) 12 hours and immediately before the procedure. Cimetidine (300 mg by intravenous push or by mouth), a nonselective histamine antagonist, and diphenhydramine (25 to 50 mg by intravenous push) may also be given. A common misconception is that a history of shellfish allergy predisposes patients to contrast media reactions. Tropomyosin, not the iodine in shellfish, appears to be the allergen.

Catheterization Protocol

A general routine for performing diagnostic catheterization will ensure efficient acquisition of all pertinent data. In general, hemodynamic measurements and determination of cardiac output should be done before angiography to reflect the basal conditions most accurately. However, in a high-risk case, the approach is to acquire the most important information first because of the possibility of patient instability.

Right-heart catheterization should not be performed in all patients undergoing routine coronary angiography because of the low yield in those with suspected coronary artery disease without other known cardiac disease. Right-heart catheterization should include screening oximetric analysis, measurement of intracardiac pressures, and determination of cardiac output. Right-heart catheterization is indicated when a patient has LV dysfunction, heart failure, complicated acute myocardial infarction, valvular heart disease, suspected pulmonary hypertension, congenital heart disease, intracardiac shunts, or pericardial disease.

Although use of a temporary pacemaker is not indicated for routine cardiac catheterization, operators should understand the techniques for proper insertion. Even in patients with an isolated left bundle branch block, right-heart catheterization can generally be performed safely with balloon flotation catheters without causing any additional conduction disturbance. An example of a balloon flotation catheter (Swan-Ganz) is shown in [Figure 19-1](#).

Catheters and Associated Equipment

Catheters used for cardiac catheterization are available in various lengths, sizes, and configurations. Typical catheter lengths vary between 50 and 125 cm, with 100 cm being used most commonly for adult left-heart catheterization via the femoral approach. In patients with a dilated ascending aorta or tortuous ascending or descending aorta, a longer 125-cm catheter is often used. The outer diameter of the catheter is specified in French units, with 1F equaling 0.33 mm. The inner luminal diameter of the catheter is smaller than the outside diameter because of the thickness of the catheter material. Guidewires used during the procedure must be the proper caliber to pass through the inner diameters of both the introducer needle and the catheter. Guidewires are described by their length in centimeters, diameter in inches, and tip conformation. A commonly used wire is a 150-cm, 0.035-inch J-tip wire. Introducer sheaths are specified by the French number of the largest catheter that can pass freely through

the inner diameter of the sheath rather than the outer diameter. Therefore a 7F introducer sheath accepts a 7F catheter (7F = 2.31 mm) but has an outer diameter greater than 7F.

Selection of the size of the catheters to be used is determined by balancing the need to opacify the coronary arteries and cardiac chambers adequately and to permit sufficient manipulation of the

catheter while limiting vascular complications and allowing earlier ambulation. The most commonly used catheters are 4F to 6F, which permit early ambulation after femoral artery access and generally provide adequate visualization. Smaller catheters require greater technical skill for manipulation and have lower flow rates. Thus their use in patients with tortuous anatomy, large body habitus, or high coronary flow states (e.g., aortic regurgitation) can be challenging. The relationship between sheath size and vascular complications is not clear within the range used for routine diagnostic catheterization. Rather, the arterial puncture technique, anticoagulation status, including the use of thienopyridines and glycoprotein IIb/IIIa receptor inhibitors, and the presence of coagulopathies are more important factors related to vascular complications.¹⁴

Right-Heart Catheterization

Right-heart catheterization allows measurement and analysis of right atrial, RV, pulmonary artery, and pulmonary capillary wedge pressure; determination of cardiac output; and screening for intracardiac shunts. Screening blood samples for oximetry should be obtained from the superior vena cava (SVC) and pulmonary artery. Right-heart catheterization is performed antegradely through either the inferior vena cava (IVC) or SVC. Percutaneous entry is achieved through the femoral, internal jugular (Video 19-1), subclavian, or antecubital veins. The anatomy of the major arteries and veins used for cardiac catheterization is shown in **Figure 19-2**.

When left-heart catheterization is performed via the Judkins (femoral artery) technique (see later), the femoral vein is used most often for access to the right side of the heart. However, when the right-heart catheter is left indwelling after the procedure, the internal jugular approach is preferable. This approach improves patient comfort and allows the patient to sit up in bed. The internal jugular approach is preferred over the subclavian to lessen the risk for pneumothorax.

Use of a micropuncture kit with a 21-gauge needle and introducer can minimize potential trauma from inadvertent puncture of the carotid artery or lung. When the jugular vein has been entered, the micropuncture assembly can be exchanged for the larger sheath (e.g., 7F) often used for right-heart catheterization. In addition, routine adjunctive use of portable vascular ultrasound probes can help locate and establish the patency of the jugular vein.

Balloon Flotation Catheters.

Balloon flotation catheters are the simplest and most widely used right-heart catheters. If thermodilution cardiac output must be determined, catheters that contain thermistors, such as Swan-Ganz catheters, are used (see **Fig. 19-1**). Intracardiac right-heart pressure and oxygen saturation to evaluate for intracardiac shunts can also be obtained. They are both flexible and flow directed. However, when the femoral approach is used, fluoroscopic guidance is usually necessary to cannulate the pulmonary artery and obtain the pulmonary capillary wedge position. Right-heart catheters have either a J-shaped or S-shaped curvature distally to facilitate passage from the SVC to the pulmonary artery or an S-shaped distal end for femoral insertion. Other right-heart balloon flotation end-hole catheters are available that are more rigid and

FIGURE 19-1 Typical Swan-Ganz catheter. The proximal ports, left to right, are the proximal injection hub, thermistor connector, distal lumen hub, and balloon inflation valve with syringe. The distal end of the catheter has a balloon and a distal end hole. The proximal injectate port exits 30 cm from the distal end of the lumen (arrow). The thermistor lies just proximal to the balloon.

FIGURE 19-2 Principal arteries used for access during cardiac catheterization. Only the superficial veins are shown on the forearm. (Modified from Thibodeau GA, Patton KT [eds]: *Anthony's Textbook of Anatomy and Physiology*. 17th ed. St. Louis, CV Mosby, 2002.)

**VIDEO 19-1**

Radial artery catheterization using Seldinger technique. Arterial entry is obtained with a micropuncture needle at a 30- to 45-degree angle into the radial artery 2-3 cm proximal to the flexor crease of the wrist. A short 0.025 wire is introduced, the needle and micropuncture are removed, and a 7-cm 5F sheath is introduced over the wire.

FIGURE 19-3 Right-heart catheterization from the femoral vein, shown in cartoon form. **Top row**, The right-heart catheter is initially placed in the right atrium (RA) aimed at the lateral atrial wall. Counterclockwise rotation aims the catheter posteriorly and allows advancement into the SVC. Although it is not evident in the figure, clockwise catheter rotation into an anterior orientation would lead to advancement into the right atrial appendage (RAA) and thereby preclude SVC catheterization. **Center row**, The catheter is then withdrawn back into the right atrium and aimed laterally. Clockwise rotation causes the tip of the catheter to sweep anteromedially and cross the tricuspid valve. With the catheter tip in a horizontal orientation just beyond the spine, it is positioned below the RV outflow (RVO) tract. Additional clockwise rotation causes the catheter to point straight up and allows advancement into the main pulmonary artery and from there into the right pulmonary artery (RPA). **Bottom row**, Two maneuvers useful in catheterization of a dilated right heart. A larger loop with a downward-directed tip may be required to reach the tricuspid valve and can be formed by catching the tip of the catheter in the hepatic vein (HV) and advancing the catheter quickly into the right atrium. The reverse loop technique (*bottom right*) gives the tip of the catheter an upward direction, aimed toward the outflow tract. PA = pulmonary artery. (From Baim DS, Grossman W: *Percutaneous approach, including transseptal and apical puncture*. In Baim DS, Grossman W [eds]: *Cardiac Catheterization, Angiography, and Intervention*. 7th ed. Philadelphia, Lea & Febiger, 2006, p 86.)

torquable and allow passage of conventional 0.035- or 0.038-inch guidewires. Although these catheters lack the ability to determine thermodilution cardiac output, they yield better pressure fidelity because of less catheter whip artifact and a larger end hole.

Two methods can be used to advance a balloon flotation catheter from the femoral vein. Frequently, the catheter can be advanced directly through the right atrium and across the tricuspid valve. Once in the right ventricle, the catheter is rotated clockwise so that it points superiorly and directly into the RV outflow tract. Once in the outflow tract, the tip of the balloon usually allows flotation into the pulmonary artery and wedge positions (**Fig. 19-3**). When necessary, deep inspiration or cough can facilitate this maneuver and assist in crossing the pulmonic valve. In patients with high pulmonary artery pressure, a guidewire can be used to stiffen the catheter and allow advancement into the wedge position. However, the operator must use caution to prevent perforation of the pulmonary artery. If the catheter continues to point inferiorly toward the RV apex, another technique should be used because further advancement can risk perforation of the RV apex.

Another technique for performing right-heart catheterization with a balloon flotation catheter is shown in **Figure 19-3**. A loop is formed in the right atrium, with the tip of the catheter directed laterally. The loop can be created by hooking the tip of the catheter on the hepatic vein or by advancing the catheter while it is directed laterally in the right atrium. Once the loop is formed, the catheter should be advanced farther, which directs the tip inferiorly and then medially across the tricuspid valve. Anterograde blood flow should then direct the catheter into the pulmonary artery. After the catheter is placed in the wedge position, the redundant loop can be removed and the balloon inflated by slow withdrawal of the catheter.

Patent Foramen Ovale Cannulation. A probe-patent foramen ovale that allows access to the left atrium is present in 20% to 30% of adult patients. It can be entered by using a multipurpose catheter with the tip directed medially and slightly posteriorly. This technique can be used in patients undergoing closure of a patent foramen ovale. The catheter is withdrawn slowly from the SVC or high right atrium until a slight forward and medial motion is observed. The catheter then prolapses into the left atrium with gentle pressure against the interatrial septum in patients with a probe-patent foramen ovale. Left atrial position can be verified by the pressure waveform, by blood samples demonstrating arterial saturation, or by hand injection of contrast medium. If left atrial access is necessary and cannot be obtained with this technique, transseptal catheterization should be undertaken (see **Transseptal Catheterization**).

Left-Heart Catheterization and Coronary Arteriography

The Judkins Technique

Because of its relative ease, speed, reliability, and low complication rate,⁹ the Judkins technique has become the most widely used method for left-heart catheterization and coronary arteriography. After local anesthesia with 1% lidocaine (Xylocaine), percutaneous entry into the femoral artery is achieved by puncturing the vessel 1 to 3 cm (or one to two fingerbreadths) below the inguinal ligament (**Fig. 19-4**). The ligament can be often palpated as it courses from the anterior superior iliac spine to the superior pubic ramus. This ligament, not the inguinal crease, should be used as the landmark. The inguinal crease can be misleading, particularly in obese patients. Another method is to use a hemostatic clamp placed under fluoroscopy to verify that the nick is made over the inferior edge of the femoral head. A small transverse skin incision is made over the femoral artery with a scalpel. In the modified Seldinger technique (**Fig. 19-5**), an 18-gauge thin-walled needle (**Fig. 19-6**) is inserted at a 30- to 45-degree angle into the femoral artery, and a 0.035- or 0.038-inch J-tip polytetrafluoroethylene (Teflon)-coated guidewire is advanced through the needle into the artery. The wire should pass freely up the aorta without tactile resistance and feel like a hot knife passing through butter.

After arterial access is obtained, a sheath at least equal in size to the coronary catheter is inserted into the femoral artery. Routine use of heparin for diagnostic cardiac catheterization has not been established. However, in prolonged procedures, such as in patients with bypass grafts or stenotic valve disease, 2000 to 3000 units may be administered by intravenous push. Routine administration of protamine after the procedure to reverse the effect of heparin is not recommended. Although rare, hypotensive reactions to protamine can be severe and are more common in patients with diabetes. In patients receiving heparin before arrival in the laboratory, an activated clotting time should be obtained after access. Removal of the sheath is not usually recommended until the activated clotting time is less than 180 seconds, unless a vascular closure device is being used.

LV systolic and end-diastolic pressure can be determined by advancing a pigtail catheter into the left ventricle (**Fig. 19-7**). In assessing valvular aortic stenosis, LV and aortic or femoral artery pressure should be recorded simultaneously with two transducers. The aortic catheter should be placed at least into the abdominal aorta rather than into the femoral artery. The attenuation in pressure can be severe in older adults with peripheral arterial disease, and estimation of aortic pressure from femoral artery pressure will be inaccurate

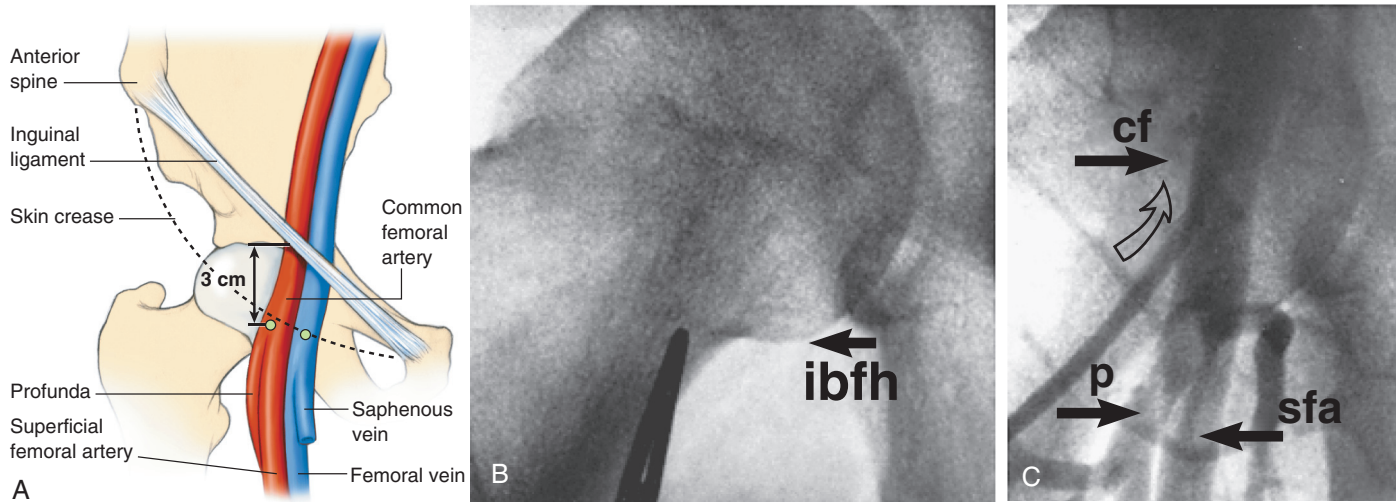

FIGURE 19-4 Regional anatomy relevant to percutaneous femoral arterial and venous catheterization. **A**, Schematic diagram showing the right femoral artery and vein coursing underneath the inguinal ligament, which runs from the anterior superior iliac spine to the pubic tubercle. The arterial skin nick should be placed approximately 3 cm below the ligament and directly over the femoral arterial pulsation; the venous skin nick should be placed at the same level but approximately one fingerbreadth more medially. Although this level corresponds roughly to the skin crease in most patients, anatomic localization relative to the inguinal ligament provides a more constant landmark. **B**, Fluoroscopic localization of the skin nick (marked by the tip of the clamp) to the inferior border of the femoral head (ibfh). **C**, A catheter (open arrow) inserted through this skin nick has entered the common femoral artery (cf), above its bifurcation into the superficial femoral artery (sfa) and profunda (p) branches. (From Baim DS, Grossman W: *Percutaneous approach, including transseptal and apical puncture*. In Baim DS, Grossman W [eds]: *Cardiac Catheterization, Angiography, and Intervention*. 7th ed. Philadelphia, Lea & Febiger, 2006, p 81.)

FIGURE 19-5 Modified Seldinger technique for percutaneous introduction of the catheter sheath. **A**, Vessel punctured by the needle. **B**, Flexible guidewire placed into the vessel through the needle. **C**, The needle removed, the guidewire left in place, and the hole in the skin around the wire enlarged with a scalpel. **D**, Sheath and dilator placed over the guidewire. **E**, Sheath and dilator advanced over the guidewire and into the vessel. **F**, Dilator and guidewire removed while the sheath remains in the vessel. (From Hill JA, Lambert CR, Vlietstra RE, Pepine CJ: *Review of general catheterization techniques*. In Pepine CJ, Hill JA, Lambert CR [eds]: *Diagnostic and Therapeutic Cardiac Catheterization*. 3rd ed. Baltimore, Williams & Wilkins, 1998, p 107.)

FIGURE 19-6 The two most commonly used needle types for vascular access. **Top**, Two-component, thin-walled Seldinger needle. **Bottom**, Single-piece, thin-walled "front-wall needle."

for determination of valvular severity. Preferentially, pigtail catheters with both a distal and a proximal lumen should be used. These specially designed catheters measure supraventricular aortic and LV pressure simultaneously when two transducers are used. In patients with suspected mitral stenosis, LV and wedge or left atrial pressure should be obtained simultaneously with two transducers.

Left ventriculography is performed in the 30-degree right anterior oblique (RAO) and 45- to 50-degree LAO views. A pigtail catheter is most commonly used for this purpose. Power injection of 30 to 40 mL of contrast medium into the ventricle at 12 to 15 mL/sec is used to assess LV function and the severity of mitral regurgitation. After ventriculography, LV systolic and end-diastolic pressure measurements may be repeated and systolic pressure recorded as the catheter is withdrawn from the left ventricle into the aorta. Obtaining both these pressures can verify whether an aortic transvalvular gradient is present. For measurement of suspected intraventricular or LV outflow

FIGURE 19-7 Technique for retrograde crossing of an aortic valve by a pigtail catheter. The **upper row** shows the technique for crossing a normal aortic valve. In the **bottom row (left)**, use of a straight guidewire and pigtail catheter in combination is shown. Increasing the length of the protruding guidewire straightens the curve of the catheter and causes the wire to point more toward the right coronary ostium; reducing the length of the protruding wire restores the pigtail contour and deflects the tip of the guidewire toward the left coronary artery. When the correct length of wire and the correct rotational orientation of the catheter have been determined, repeated advancement and withdrawal of the catheter and guidewire together allow retrograde passage across the valve. In a dilated aortic root (**bottom row, middle**), an angled pigtail catheter is preferable. In a small aortic root (**bottom row, right**), a right coronary Judkins catheter may have advantages. In patients with bicuspid valves, an Amplatz left catheter is often used because it directs the wire more superiorly. (From Baim DS, Grossman W: *Percutaneous approach including transseptal and apical puncture*. In Baim DS, Grossman W [eds]: *Cardiac Catheterization, Angiography, and Intervention*. 6th ed. Philadelphia, Lea & Febiger, 2006, p 93.)

tract gradients, a multipurpose catheter with an end hole is desirable to localize the gradient in the left ventricle. Pigtail catheters contain side holes, which obscures the capacity to define whether the gradient is intraventricular, subvalvular, and/or transvalvular.

Postprocedure Care

After coronary arteriography and left-heart catheterization have been completed, the catheters are removed; if manual compression is used, firm pressure is applied to the femoral area for 10 minutes. The patient should be instructed to lie in bed for several hours with the leg remaining straight to prevent hematoma formation. With 4F to 6F catheters, 2 hours of bed rest is usually sufficient, whereas use of catheters larger than 6F generally requires at least 3 to 4 hours.

Alternatively, vascular closure devices may be used. Four types are currently available commercially: collagen plugs, suture closure, metallic clips, and hemostatic patches. Each allows early ambulation of patients, within 1 to 2 hours after the procedure, and a shorter time until hemostasis than with manual compression.¹⁵⁻¹⁹ They also permit early removal of the sheath in patients receiving anticoagulation. Although one meta-analysis raised concern about the increased risk for pseudoaneurysm and hematoma with arterial puncture closure devices,²⁰ another study demonstrated a lower incidence of vascular complications than with manual compression.²¹ The ultimate success of any means of achieving hemostasis often relies on a single front-wall puncture of the common femoral artery in the segment below the inguinal ligament and over the femoral head.

The main advantage of the Judkins technique is speed and ease of selective catheterization. These attributes do not, however, preclude the importance of extensive operator experience to ensure quality studies with acceptable safety. The main disadvantage of this technique is its complexity in patients with severe iliofemoral atherosclerotic disease, in whom retrograde passage of catheters through areas of extreme narrowing or tortuosity may be difficult or impossible. However, with careful technique, fluoroscopic guidance, and torquable floppy-tipped wires (e.g., Wholey, Glidewire), passage through

challenging anatomy or synthetic aortofemoral grafts can be achieved with low complication rates.

Percutaneous Radial Artery Technique

Left-heart catheterization by the radial artery approach was developed as an alternative to the percutaneous transbrachial approach in an attempt to limit vascular complications. The inherent advantages of the transradial approach are that the hand has a dual arterial supply connected through the palmar arches and that no nerves or veins are located at the site of puncture. In addition, bed rest is unnecessary after the procedure, thereby allowing more efficient outpatient angiography.

The procedure requires a normal Allen test result. The Allen test consists of manual compression of both the radial and ulnar arteries during fist clenching until the hand is blanched. Normal color returns to the opened hand within 10 seconds after release of pressure over the ulnar artery, and significant reactive hyperemia is absent on release of pressure over the radial artery. The use of pulse oximetry (Barbeau test) can improve the accuracy and reproducibility of establishing adequate dual-supply blood flow.

In the radial technique (Video 19-2), the arm is abducted and the wrist hyperextended over a gauze roll. Routine skin anesthesia is used. A micropuncture needle (anterior wall technique) or a 20-gauge Angiocath (posterior wall technique) is introduced at a 30- to 45-degree angle into the radial artery 2 to 3 cm proximal to the flexor crease of the wrist. A 7- to 16-cm-long 4F or 5F sheath is then introduced over a short 0.025-inch wire. Next, approximately 10 mL of blood is drawn into a syringe containing heparin (3000 to 5000 units), and vasodilators (e.g., 200 µg of nicardipine plus 100 µg of nitroglycerin) are added and administered intra-arterially to prevent radial artery spasm. The cocktail is mixed with blood to minimize the burning sensation and then injected through the side arm of the sheath. Coronary catheters are then advanced over a standard 0.035-inch J-tip exchange wire into the ascending aorta. The left and right coronary arteries are cannulated in a manner similar to the brachial approach. Hemostasis is achieved at the end of the procedure after removal of the sheath with use of direct pressure or an inflatable balloon cuff. It is recommended that the arterial puncture site be allowed to bleed for several beats before maintaining direct pressure. The radial pulse should be monitored regularly for several hours after the procedure.

Potential limitations of this access include an inability to cannulate the radial artery because of its smaller size and propensity for the development of spasm, poor visualization of the coronary arteries as a result of the small-caliber catheters, limited manipulation potential, and risk for radial arterial occlusion secondary to dissection or thrombus formation. If intervention is contemplated, selection of the device may be limited by guide catheter size. The transradial approach for left-heart catheterization has gained in popularity.²²⁻²⁴ A recent randomized trial of 7021 patients with acute coronary syndromes undergoing coronary angiography and interventional procedures demonstrated no difference in non-CABG-related major bleeding at 30 days, but a reduction in large hematomas and pseudoaneurysm.²⁰ In an analysis of 294,769 patients undergoing PCI for STEMI at 1204 hospitals in the NCDR CathPCI Registry between 2007 and 2011, patients were grouped according to the access site used for PCI. The temporal trend in the rate of use of the radial versus femoral approach was determined. Over a 5-year period, use of transradial versus femoral access in patients with STEMI increased from 0.9% to 6.4% ($P < 0.0001$). Transradial access was associated with longer median door-to-balloon time (78 versus 74 minutes; $P < 0.0001$) but lower adjusted risk for bleeding (odds ratio [OR], 0.62; 95% confidence interval [CI], 0.53 to 0.72; $P < 0.0001$) and lower adjusted risk for in-hospital mortality (OR, 0.76; 95% CI, 0.57 to 0.99; $P = 0.0455$).²⁴

Percutaneous Brachial Artery Technique. The brachial technique has largely been replaced by the radial technique. This technique uses the Seldinger method of percutaneous brachial artery entry. A 4F to 6F sheath is placed into the brachial artery, and 3000 to 5000 units of heparin is infused into the side port. A guidewire is then advanced to the ascending aorta under fluoroscopic control. The guidewire may occasionally be necessary to direct the left coronary

**VIDEO 19-2**

Right heart catheterization is performed via a 7F sheath in the right internal jugular vein. A 7F balloon-tipped flotation catheter is advanced from the superior vena cava, right atrium, right ventricle, main pulmonary artery, and right pulmonary artery into the pulmonary capillary wedge position.

catheter into the left sinus of Valsalva and the ostium of the left main coronary artery. After removal of the sheath, the arm should be maintained straight with an arm board for 4 to 6 hours along with observation of the radial and brachial pulses.

The main advantage of the percutaneous brachial technique is that it avoids a brachial artery cutdown and the brachial artery is generally larger than the radial artery. When compared with the femoral technique, patients' comfort, hemostasis time, and time to ambulation favor the radial over the brachial technique. Procedural efficiency, radiation exposure, and diagnostic image quality are more favorable with the femoral approach.

Brachial Artery Technique: Sones Technique. Sones and colleagues introduced the first technique for coronary artery catheterization by means of a brachial artery cutdown. The technically demanding Sones technique is still used in some centers and is described in [Chapter 20](#).

Transseptal Catheterization. Transseptal left-heart catheterization has become more prevalent as a result of percutaneous balloon mitral commissurotomy as a preferential option to surgical commissurotomy ([see Chapter 63](#)), electrophysiologic procedures requiring access to pulmonary veins ([see Chapter 38](#)), and use of percutaneous mitral valve repair ([see Chapter 56](#)). Transseptal catheterization can be performed with a complication rate lower than 1% in experienced centers.²⁵⁻²⁷

An 8F Mullins or SL transseptal sheath and dilator combination is used. The Brockenbrough needle is an 18-gauge needle that tapers to 21 gauge at the distal tip ([Fig. 19-8](#)). The needle is placed in the transseptal sheath. One commonly used approach is to place a 0.032-inch guidewire through the femoral vein and right atrium into the

SVC. The Mullins or transseptal sheath and dilator are then advanced over the wire into the SVC. The guidewire is removed and replaced with a Brockenbrough needle. The distal port is connected to a pressure manifold. With the tip of the needle just proximal to the tip of the Mullins sheath, the entire catheter system is withdrawn. The catheter is simultaneously rotated from a 12 o'clock to a 5 o'clock position. The operator observes two abrupt rightward movements. The first occurs as the catheter descends from the SVC to the right atrium. The second occurs as the tip of the transseptal dilator passes over the limbic edge into the fossa ovalis. The dilator and needle are then advanced gently as a unit. Steady gentle pressure is sometimes adequate to advance the system through the fossa ovalis into the left atrium. If not, the needle should be advanced across the interatrial septum while the sheath is held in place. In cases in which transseptal puncture is technically difficult because of a large right atrium, post-surgical condition, or anatomic variant, intracardiac or transesophageal echocardiography can be useful to localize the fossa ovalis and interatrial septum^{26,28} ([see Intracardiac Echocardiography](#)).

Left atrial position can be confirmed by the overall increase in pressure with left atrial *a* and *v* waveforms, hand injection of contrast medium, or measurement of arterial oxygen saturation. When its position is confirmed, the catheter should be rotated toward the 3 o'clock position and the dilator and sheath safely advanced 2 to 3 cm into the left atrium. The sheath is held firmly, and the dilator and needle are removed. Left atrial pressure measurements should then be repeated. If measurement of LV pressure or left ventriculography is necessary, the catheter can usually be advanced easily into the left ventricle after slight counterclockwise rotation. The major risk associated with transseptal catheterization lies in inadvertent puncture of atrial structures, such as the atrial free wall, left atrial appendage, coronary sinus, aortic root, or pulmonary artery.

Direct Transthoracic Left Ventricular Puncture. The only diagnostic indication for direct LV puncture is to measure LV pressure and perform ventriculography in patients with mechanical prosthetic valves in both the mitral and aortic positions that prevent both retrograde arterial and transseptal catheterization. Crossing of tilting disc valves with a catheter should be avoided because of the risk for catheter entrapment, occlusion of the valve, or possible dislodgment and embolization of the disc.

The procedure is performed after localization of the LV apex by palpation or, preferably, by echocardiography.²⁹ After local anesthesia is administered, an 18- or 21-gauge 6-inch Teflon catheter system is inserted at the upper rib margin and directed slightly posteriorly and toward the right second intercostal space until the impulse is encountered. The needle and sheath are advanced into the left ventricle. The stylet and needle are removed, and the sheath is connected for pressure measurement.

Risks related to this procedure include cardiac tamponade, hemothorax, pneumothorax, laceration of the left anterior descending coronary artery, embolism of LV thrombus, vagal reactions, and ventricular arrhythmias. The risk for pericardial tamponade, however, is limited in patients who have previously undergone cardiac surgery because mediastinal fibrosis is present. With the multiple noninvasive imaging techniques available, including transesophageal echocardiography and CMR, this procedure is rarely indicated.

The transapical approach to aortic valve implantation uses a similar technique except with open exposure of the LV apex. This is used as an alternative access when the femoral artery dimensions are inadequate to accommodate the larger sheath ([see Chapter 56](#)). Direct visualization of the LV apex is accomplished with an intercostal incision followed by apical puncture using the Seldinger technique.

Endomyocardial Biopsy

Endomyocardial biopsy is performed most commonly with various disposable or, less frequently, with reusable biotomes. The most popular devices used for the internal jugular vein approach include preshaped 50-cm biotomes. RV biopsy may be performed with use of the internal jugular vein ([see Right-Heart Catheterization](#) for the internal jugular technique), the subclavian vein, or the femoral vein. LV biopsy is not commonly performed and uses the femoral arterial approach.

When RV biopsy is performed through the right internal jugular vein, a 7F short straight sheath or long curved sheath is introduced by the usual Seldinger technique. If a short sheath is used, a 7F biotome is advanced under fluoroscopic guidance to the lateral wall of the right atrium. With counterclockwise rotation, the device is

FIGURE 19-8 Transseptal catheters. **A**, Distal catheter. **B**, Proximal catheter. *Right*, Mullins transseptal sheath. *Middle*, Introducer (dilator) placed inside the sheath to add stiffness to the catheter. *Left*, Brockenbrough transseptal needle that is placed inside the sheath and used to penetrate the septum.

advanced across the tricuspid valve and toward the interventricular septum. When a long preshaped sheath is used, it is positioned against the RV septum. RV pressure should be monitored continuously. The bioptome is passed through the sheath, and samples are obtained. Alternatively, two-dimensional echocardiography rather than fluoroscopy has been used to guide the position of the bioptome.

Contact with the myocardium is confirmed by the presence of premature ventricular contractions, resistance to further advancement, and transmission of the ventricular impulse to the operator. The bioptome is then withdrawn slightly from the septum, the jaws of the forceps are opened, the bioptome is readvanced to make contact with the myocardium, and the forceps is closed. A slight tug is felt on removal of the device. Four to six samples of myocardium are usually required for adequate pathologic analysis. Preprocedure consultation with a pathologist or transplant cardiologist should be obtained to ensure appropriate specimen collection and processing.

RV biopsy from the femoral vein requires the insertion of a long 7F sheath directed toward the portion of the ventricle to be sampled. Various sheath configurations are used for RV biopsy. The conventional sheath has a 45-degree angle on its distal end to allow access to the right ventricle. However, specifically designed sheaths have dual curves. These catheters possess the usual 180-degree curve and an additional distal perpendicular septal plane curve of 90 degrees, which permit improved manipulation and positioning toward the interventricular septum. This sheath configuration can also be used from the internal jugular approach.

Whatever access is used, the bioptome is advanced through the sheath and should be visualized on both the 30-degree RAO and 40-degree LAO views. The RAO view ensures that the catheter is in the midventricle away from the apex. The LAO view verifies that the tip of the sheath is oriented toward the interventricular septum. Infusion of contrast material through the side port of the sheath can help confirm position. Samples of myocardium are taken in a manner similar to that described earlier.

If LV biopsy is performed, the biopsy sheath is generally inserted through the femoral artery and positioned over a multipurpose or

pigtail catheter that has been placed in the ventricle. The sheath is advanced below the mitral apparatus and away from the posterobasal wall. The catheter is then withdrawn, and a long LV bioptome is inserted. Care must be taken when LV biopsy is performed to prevent air embolism while the bioptome is being introduced into the sheath. A constant infusion of flush solution through the sheath minimizes the risk for air or thrombus embolism.

Complications of endomyocardial biopsy include cardiac perforation with tamponade, emboli (air, tissue, or thromboembolus), arrhythmias, electrical conduction disturbances, injury to the tricuspid valve, vasovagal reactions, and pneumothorax. The overall complication rate is between 1% and 3%; risk for cardiac perforation with tamponade is generally reported to be less than 0.05%.³⁰⁻³² Endomyocardial biopsy is the most common cause of severe tricuspid regurgitation after cardiac transplantation.³³ The use of longer sheaths dramatically decreases the incidence of anatomic disruption of the valve during biopsy.

Systemic embolization and ventricular arrhythmias are more common with LV biopsy. LV biopsy should generally be avoided in patients with right bundle branch block because of potential for the development of complete atrioventricular block, as well as in patients with known LV thrombus.

The role of endomyocardial biopsy in the management of cardiovascular disease has been defined.³² Two class I indications for endomyocardial biopsy are recognized (**Table 19-2**). The first is new-onset heart failure of less than 2 weeks' duration associated with either normal or enlarged LV size and hemodynamic compromise (**see Chapter 67**). The second is new-onset heart failure of up to 3 months' duration complicated by LV dilation, new ventricular arrhythmias, advanced heart block, or failure to respond to usual care within 2 weeks. The use of biopsy for suspected anthracycline toxicity or restrictive disease is considered a class IIa indication.³² Cardiac transplant monitoring for rejection is the most common indication for biopsy (**see Chapter 28**).

Percutaneous Intra-aortic Balloon Pump Insertion

Intra-aortic balloon counterpulsation devices are positioned in the descending thoracic aorta. They have a balloon volume of 30 to

TABLE 19-2 The Role of Endomyocardial Biopsy in 14 Clinical Scenarios

CLINICAL SCENARIO	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
New-onset heart failure of <2 weeks' duration associated with a normal-sized or dilated left ventricle and hemodynamic compromise	I	B
New-onset heart failure of 2 weeks' to 3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 2 weeks	I	B
Heart failure >3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 2 weeks	IIa	C
Heart failure associated with dilated cardiomyopathy of any duration and suspected allergic reaction and/or eosinophilia	IIa	C
Heart failure associated with suspected anthracycline-induced cardiomyopathy	IIa	C
Heart failure associated with unexplained restrictive cardiomyopathy	IIa	C
Suspected cardiac tumors	IIa	C
Unexplained cardiomyopathy in children	IIa	C
New-onset heart failure of 2 weeks' to 3 months' duration associated with a dilated left ventricle, without new ventricular arrhythmias or second- or third-degree heart block, that responds to usual care within 2 weeks	IIb	B
Heart failure >3 months' duration associated with a dilated left ventricle, without new ventricular arrhythmias or second- or third-degree heart block, that responds to usual care within 2 weeks	IIb	C
Heart failure associated with unexplained hypertrophic cardiomyopathy	IIb	C
Suspected arrhythmogenic RV dysplasia	IIb	C
Unexplained ventricular arrhythmias	IIb	C
Unexplained atrial fibrillation	III	C

50 mL, use helium as the inflation gas, and are timed to inflate during diastole and deflate during systole. Balloon size is based on the patient's height. The device is inserted through the femoral artery via the standard Seldinger technique with the use of 7F to 8F systems so that the tip is 2 to 3 cm below the level of the left subclavian artery. Optimal positioning requires fluoroscopic guidance. Timing of the balloon using the ECG or pressure tracing is adjusted during 1:2 (one inflation for each two beats) pumping so that inflation of the balloon occurs at the aortic dirotic notch and deflation occurs immediately before systole. Such timing ensures maximal augmentation of diastolic flow and maximal systolic unloading. **Figure 19-9** displays the optimal timing of an intra-aortic balloon pump (IABP).³⁴

Favorable hemodynamic effects include a reduction in LV afterload and improvement in myocardial oxygenation.³⁵ IABP insertion is indicated for patients with angina refractory to medical therapy, cardiogenic shock, or mechanical complications of myocardial infarction (including severe mitral regurgitation and ventricular septal defect) or for those who have severe left main coronary artery stenosis. An IABP may also be valuable in patients undergoing high-risk PCI or after primary angioplasty in the setting of acute myocardial infarction.³⁶ IABP insertion is contraindicated in patients with moderate or severe aortic regurgitation, aortic dissection, aortic aneurysm, patent ductus arteriosus, severe peripheral vascular disease, bleeding disorders, or sepsis.

Complications of IABP insertion include limb ischemia requiring early balloon removal or vascular surgery, balloon rupture, balloon entrapment, hematomas, and sepsis.^{35,36} The incidence of vascular complications ranges from 12% to higher than 40%. Most patients in whom limb ischemia develops after insertion of an IABP have resolution of the ischemia on balloon removal and do not require surgical intervention (thrombectomy, vascular repair, fasciotomy, or amputation). Risk for limb ischemia is heightened in patients with diabetes or peripheral arterial disease, in women, and in patients with a post-insertion ankle-brachial index lower than 0.8. However, with the use of smaller catheters (7F), vascular complications are markedly reduced.

HEMODYNAMIC DATA

The hemodynamic component of the cardiac catheterization procedure focuses on pressure measurements, measurement of flow (e.g., cardiac output, shunt flow, flow across a stenotic orifice, regurgitant flow, and coronary blood flow), and determination of vascular resistance. Simply stated, flow through a blood vessel is determined by the pressure difference within the vessel and vascular resistance as described by Ohm's law: $Q = \Delta P/R$.

Pressure Measurements

Accurate recording of pressure waveforms and correct interpretation of the physiologic data derived from these waveforms are major goals of cardiac catheterization. A pressure wave is the cyclical force generated by cardiac muscle contraction, and its amplitude and duration are influenced by various mechanical and physiologic parameters. The pressure waveform from a particular cardiac chamber is influenced by the force of the contracting chamber and its surrounding structures, including the contiguous chambers of the heart, pericardium, lungs, and vasculature. Physiologic variables of heart rate and the respiratory cycle also influence the pressure waveform. An understanding of the components of the cardiac cycle is essential for correct interpretation of hemodynamic data obtained in the catheterization laboratory.

Pressure Measurement Systems

Fluid-Filled Systems. Intravascular pressure is typically measured with the use of a fluid-filled catheter attached to a pressure transducer. The pressure wave is transmitted from the tip of the catheter to the transducer by the fluid column within the catheter. Most pressure transducers are disposable electrical strain gauges. The pressure wave distorts the diaphragm or wire within the transducer. This energy

is then converted to an electrical signal proportional to the pressure being applied by using the principle of the Wheatstone bridge. This signal is then amplified and recorded as an analog signal.³⁷

There are a number of sources of error when pressure is measured with a fluid-filled catheter-transducer system. Distortion of the output signal occurs as a result of the frequency response characteristics and damping characteristics of the system. The frequency response of the system is the ratio of the output amplitude to input amplitude over a range of frequencies of the input pressure wave. The natural frequency is the frequency at which the system oscillates when it is shock-excited in the absence of friction. Dissipation of the energy of the system, such as by friction, is called damping. To ensure a high-frequency response range, the pressure measurement system should have the highest possible natural frequency and optimal damping. With optimal damping the energy is dissipated gradually, thus maintaining the frequency response curve as close as possible to an output-input ratio of 1 as it approaches the system's natural frequency. Optimal damping is achieved by using a short, wide-bore, noncompliant catheter-tubing system that is directly connected to the transducer, along with the use of a low-density liquid from which all air bubbles have been removed.

The pressure transducer must be calibrated against a known pressure, and establishment of a zero reference must be undertaken at the start of the catheterization procedure. To "zero" the transducer, the transducer is placed at the level of the atria, which is approximately midchest. If the transducer is attached to the manifold and variable positions during the procedure, a second fluid-filled catheter system should be attached to the transducer and positioned at the midchest level. All transducers being used during the procedure should be zeroed and calibrated simultaneously. Because of the possibility of variable drift during the procedure, all transducers should be rebalanced immediately before simultaneous recordings of the transvalvular gradient or simultaneous pressure determinations are obtained.

Potential sources of error include catheter whip artifact (motion of the tip of the catheter within the measured chamber), end-pressure artifact (an end-hole catheter measures an artificially elevated pressure because of streaming or high velocity of the pressure wave), catheter impact artifact (when the catheter is struck by the walls or valves of the cardiac chambers), and obstruction of the tip of the catheter within small vessels or valvular orifices or against the wall of the vessel. The operator must be aware of the many potential sources of error, and when there is a discrepancy between the observed data and the clinical scenario, all components of the system should be examined for errors or artifacts.

Micromanometer Catheters. The use of micromanometer catheters, which have the pressure transducer mounted at the tip, greatly reduces many of the errors inherent in fluid-filled systems. However, their usefulness is limited by the additional cost and time needed for proper calibration and use of the system. These catheters have higher natural frequencies and more optimal damping characteristics because the interposing fluid column is eliminated. In addition, the incidence of catheter whip artifact is decreased. The pressure waveform is less distorted and is without the 30- to 40-millisecond delay seen with the fluid-filled catheter-transducer system. Commercially available high-fidelity micromanometer systems have both an end hole and side holes to allow over-the-wire insertion into the circulation while also permitting angiography. Catheters that have two transducers separated by a short distance are useful for accurate measurement of gradients across valvular structures and within ventricular chambers. The micromanometer system has been used to assess the rate of rise in ventricular pressure (dP/dt), wall stress, rate of decay in ventricular pressure ($-dP/dt$), time constant of relaxation (τ), and ventricular pressure-volume relationships (see **Chapter 27**).

Normal Pressure Waveforms

An understanding of normal pressure waveform morphologies is necessary to comprehend the abnormalities that characterize certain pathologic conditions. Normal pressures in the cardiac chambers and great vessels are listed in **Table 19-3**. Simply stated, whenever fluid is added to a chamber or compressed within a chamber, the pressure usually rises. Conversely, whenever fluid exits from a chamber or the chamber relaxes, the pressure usually falls. One exception to this rule is the early phase of LV diastolic filling, when LV volume increases after mitral valve opening but LV pressure continues to decrease because of active relaxation. Examples of normal pressure waveforms are shown in **Figure 19-10**.

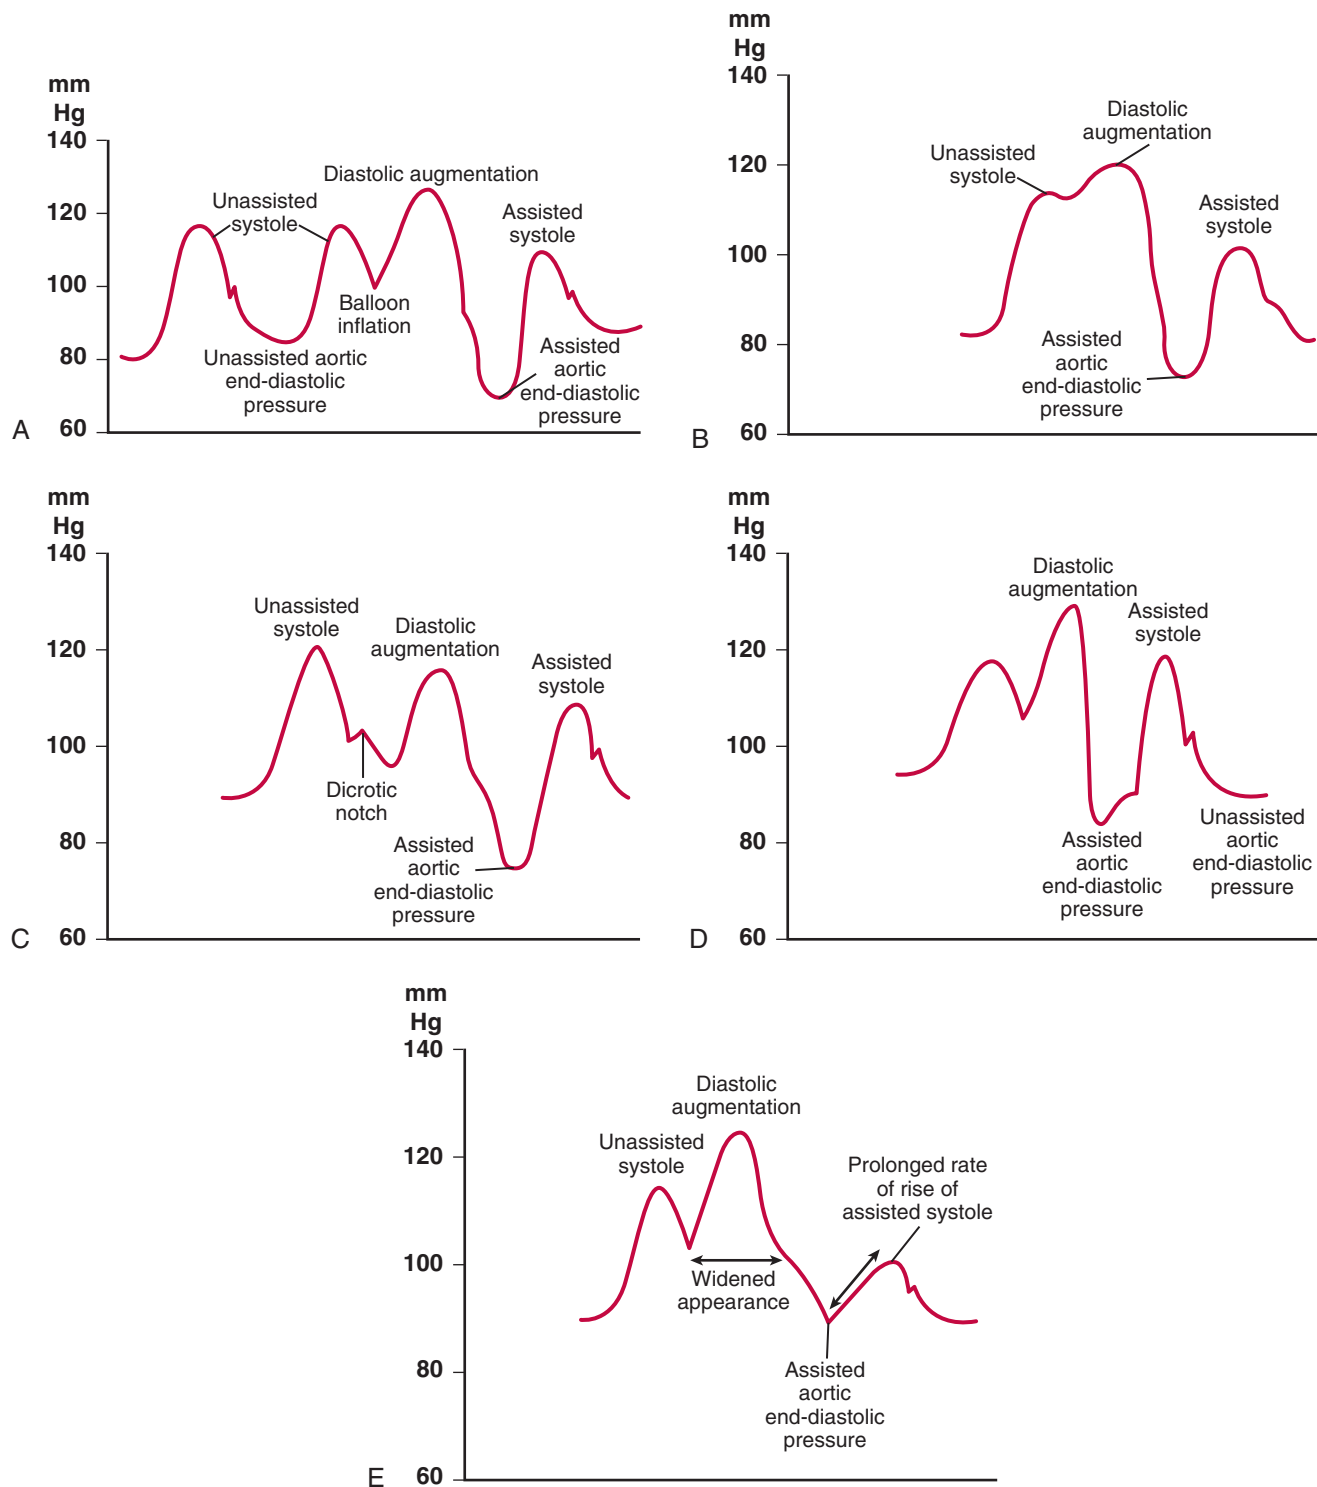

FIGURE 19-9 A, Optimal timing and arterial waveforms with an IABP. A systemic arterial pressure waveform is shown from a patient with a normally functioning IABP device that is programmed to inflate during every other cardiac cycle (commonly referred to as 1:2 inflation). With the first beat, aortic systolic and end-diastolic pressures are shown without IABP support and are therefore unassisted. With the second beat, the balloon inflates with the appearance of the dicrotic notch, and peak-augmented diastolic pressure is inscribed. With balloon deflation, assisted end-diastolic pressure and assisted systolic pressure are observed. To confirm that the IABP is producing maximal hemodynamic benefit, the peak diastolic augmentation should be greater than the unassisted systolic pressure, and the two assisted pressures should be less than the unassisted values. **B**, Systemic arterial pressure waveform from a subject in whom balloon inflation occurs too early, before aortic valve closure. Consequently, the left ventricle is forced to empty against an inflated balloon; the corresponding increase in afterload may increase myocardial oxygen demand and worsen systolic function. **C**, Systemic arterial pressure waveform from a patient in whom balloon inflation occurs too late, well after the beginning of diastole, thereby minimizing diastolic pressure augmentation. **D**, Systemic arterial pressure waveform from a patient in whom balloon deflation occurs too early, before the end of diastole. This may shorten the period of diastolic pressure augmentation. A corresponding transient decrease in aortic pressure may promote retrograde arterial flow from the carotid or coronary arteries and possibly induce cerebral or myocardial ischemia. **E**, Systemic arterial pressure waveform from a subject in whom balloon deflation occurs too late, after the end of diastole, thereby producing the same deleterious consequences as early balloon inflation (increased LV afterload with a resultant increase in myocardial oxygen demand and worsening of systolic function). (From Trost JC, Hillis LD: Intra-aortic balloon counterpulsation. *Am J Cardiol* 97:1391, 2006.)

Atrial Pressure

The right atrial pressure waveform has three positive deflections, the *a*, *c*, and *v* waves. The *a* wave is due to atrial systole and follows the P wave on the ECG. The height of the *a* wave depends on atrial contractility and resistance to RV filling. The *x* descent follows the *a* wave and represents relaxation of the atrium and downward pulling of the tricuspid annulus by RV contraction. The *x* descent is interrupted by the *c* wave, which is a small positive deflection caused by protrusion of the closed tricuspid valve into the right atrium. Pressure in the atrium rises after the *x* descent as a result of passive atrial filling. Atrial pressure then peaks as the *v* wave, which represents RV systole. The height of the *v* wave is related to atrial compliance and the

amount of blood returning to the atrium from the periphery. The right atrial *v* wave is generally smaller than the *a* wave. The *y* descent occurs after the *v* wave and reflects opening of the tricuspid valve and emptying of the right atrium into the right ventricle. During spontaneous respiration, right atrial pressure declines during inhalation as intrathoracic pressure falls. Right atrial pressure rises during exhalation as intrathoracic pressure increases. The opposite effect is seen when patients are mechanically ventilated.

The left atrial pressure waveform is similar to that of the right atrium, although normal left atrial pressure is higher because of the high-pressure system of the left side of the heart. In the left atrium, as opposed to the right atrium, the *v* wave is generally higher than the *a* wave. This difference is due to the fact that the left atrium is constrained posteriorly by the pulmonary veins whereas the right atrium can easily decompress throughout the IVC and SVC. The height of the left atrial *v* wave most accurately reflects left atrial compliance.

TABLE 19-3 Normal Pressure and Vascular Resistance Values

PRESSURE	AVERAGE (mm Hg)	RANGE (mm Hg)
Right atrium		
<i>a</i> wave	6	2-7
<i>v</i> wave	5	2-7
Mean	3	1-5
Right ventricle		
Peak systolic	25	15-30
End-diastolic	4	1-7
Pulmonary artery		
Peak systolic	25	15-30
End-diastolic	9	4-12
Mean	15	9-19
Pulmonary capillary wedge		
Mean	9	4-12
Left atrium		
<i>a</i> wave	10	4-16
<i>v</i> wave	12	6-21
Mean	8	2-12
Left ventricle		
Peak systolic	130	90-140
End-diastolic	8	5-12
Central aorta		
Peak systolic	130	90-140
End-diastolic	70	60-90
Mean	85	70-105
VASCULAR RESISTANCE	MEAN (dyne-sec • cm ⁻⁵)	RANGE (dyne-sec • cm ⁻⁵)
Systemic vascular resistance	1100	700-1600
Total pulmonary resistance	200	100-300
Pulmonary vascular resistance	70	20-130

Pulmonary Capillary Wedge Pressure

The pulmonary capillary wedge pressure waveform is similar to the left atrial pressure waveform but is slightly damped and delayed as a result of transmission through the lungs. The *a* and *v* waves with both *x* and *y* descents are visible, but *c* waves may not be seen. In the normal state, pulmonary artery diastolic pressure is similar to mean pulmonary capillary wedge pressure because the pulmonary circulation has low resistance. In certain disease states associated with elevated PVR (hypoxemia, pulmonary embolism, and chronic pulmonary hypertension) and occasionally after mitral valve surgery, pulmonary capillary wedge pressure may overestimate true left atrial pressure. In this circumstance, accurate measurement of the mitral valve gradient may require that direct left atrial pressure be obtained.

Ventricular Pressure

RV and LV waveforms are similar in morphology. They differ mainly with respect to their magnitudes. The durations of systole and isovolumic contraction and relaxation are longer and the ejection period is shorter in the left than in the right ventricle. There may be a small (5 mm Hg) systolic gradient between the right ventricle and pulmonary artery. Ventricular diastolic pressure is characterized by an early rapid filling wave, during which most of the ventricle fills; a slow filling phase; and the *a* wave, which denotes atrial systolic activity. End-diastolic pressure is generally measured at the C point, which is the rise in ventricular pressure at the onset of isovolumic contraction. When the C point is not well seen, a line drawn from the R wave on the simultaneous ECG to the ventricular pressure waveform is used as end-diastolic pressure.

Great Vessel Pressure

The contour of the central aortic pressure and the pulmonary artery pressure tracing consists of a systolic wave, the incisura (indicating closure of the semilunar valves), and a gradual decline in pressure until the following systole. Pulse pressure reflects stroke volume and compliance of the arterial system. Mean aortic pressure more accurately reflects peripheral resistance. As the systemic pressure wave is transmitted through the length of the aorta, the systolic wave increases in amplitude and becomes more triangular, and the diastolic wave decreases until it reaches the midthoracic aorta and then increases. Mean aortic pressures, however, are usually similar; mean peripheral arterial pressure is typically lower than mean central aortic pressure by 5 mm Hg or less.

FIGURE 19-10 Normal right- and left-sided heart pressures recorded from fluid-filled catheter systems in a human. (From Pepine C, Hill JA, Lambert CR [eds]: *Diagnostic and Therapeutic Cardiac Catheterization*. 3rd ed. Baltimore, Williams & Wilkins, 1998.)

The difference in systolic pressure between the central aorta and the periphery (femoral, brachial, or radial arteries) is greatest in younger patients because of their increased vascular compliance. These potential differences between the proximal aorta and peripheral artery must be considered for accurate measurement and interpretation of the peak systolic pressure gradient between the left ventricle and the systemic arterial system in patients with suspected aortic stenosis. When a transvalvular gradient is present, the most accurate measure of aortic pressure is obtained at the level of the coronary arteries. This measurement avoids the effect of pressure recovery, which is defined as the variable increase in lateral pressure downstream from a stenotic orifice (see Chapter 14). This approach

can become clinically important in patients with mild to moderate aortic stenosis, particularly when the aorta is small. The transvalvular gradient will be underestimated and aortic valve area overestimated because of higher pressure in the femoral artery in younger patients when supraventricular pressure is not obtained. This can be avoided with a dual-lumen pigtail catheter, which measures pressure in the left ventricle and ascending aorta simultaneously.

Abnormal Pressure Characteristics

Abnormal pressure waveforms may be diagnostic of specific pathologic conditions. Table 19-4 summarizes the more commonly encountered waveforms.

Cardiac Output Measurements

No method of measuring cardiac output is completely accurate in all patients, but it can be estimated on the basis of various assumptions. The two most commonly used techniques are the thermodilution and Fick methods. For comparison among patients, cardiac output is often corrected for the patient's size on the basis of body surface area and expressed as the cardiac index.

Thermodilution Techniques. The thermodilution procedure requires injection of a bolus of liquid (usually normal saline) into the proximal port of the catheter. The resultant change in temperature of the liquid is measured by a thermistor mounted in the distal end of the catheter. The change in temperature versus time is graphed. Cardiac output is then calculated with an equation that considers the temperature and specific gravity of the injectate and the temperature and specific gravity of the blood along with the injectate volume. A calibration factor is also used. Cardiac output is inversely related to the area under a thermodilution curve, shown as a function of temperature versus time, with a smaller area under the curve being indicative of higher cardiac output (Fig. 19-11). Temperature fluctuation in

the circuit can affect accuracy, however, so the use of two thermistors can significantly improve the accuracy of this technique.³⁸

The thermodilution method has several advantages. It obviates the need for withdrawal of blood from an arterial site and is less affected by recirculation. Perhaps its greatest advantage is the rapid display of results with computerized methods. However, significant error occurs in patients with severe tricuspid or pulmonary regurgitation. Also, in patients with low output (especially <2.5 liter/min), thermodilution tends to overestimate cardiac output.

Fick Method. The Fick principle estimates cardiac output by using the assumption that pulmonary blood flow (PBF) is equal to systemic blood flow (SBF) in the absence of an intracardiac shunt. The basic principle is that flow of blood is proportional to the difference in the concentration of oxygen between arterial and venous blood and the rate of oxygen uptake by red blood cells from the lungs (Fig. 19-12). The same number of red blood cells that enter the lung must leave the lung if no intracardiac shunt is present. Thus if certain parameters are known (the number of oxygen molecules attached to red blood cells entering the lung, the number of oxygen molecules attached to

FIGURE 19-11 Thermodilution cardiac output curves. A normal curve has a sharp upstroke after an injection of saline. A smooth curve with a mildly prolonged downslope occurs until it is back to baseline. The area under the curve is inversely related to cardiac output. At low cardiac output, a prolonged period is required to return to baseline. Therefore the area under the curve is larger. In a high cardiac output state, the cooler saline injectate moves faster through the right side of the heart, and temperature returns to baseline more quickly. The area under the curve is smaller and the output is higher.

FIGURE 19-12 Schematic illustration showing measurement of flow by the Fick principle. Fluid containing a known concentration of an indicator (C_{in}) enters a system at flow rate Q . As the fluid passes through the system, indicator is continuously added at rate \dot{V} , thereby raising the concentration in the outflow to C_{out} . In a steady state the rate of indicator leaving the system (QC_{out}) must equal the rate at which it enters (QC_{in}) plus the rate at which it is added (\dot{V}). When oxygen is used as the indicator, cardiac output can be determined by measuring oxygen consumption (\dot{V}_{O_2}), arterial oxygen content (CaO_2), and mixed venous oxygen content (CvO_2). (From Winniford MD, Kern MJ, Lambert CR: *Blood flow measurement*. In Pepine CJ, Hill JA, Lambert CR [eds]: *Diagnostic and Therapeutic Cardiac Catheterization*. 3rd ed. Baltimore, Williams & Wilkins, 1998, p 400.)

red blood cells leaving the lung, and the number of oxygen molecules consumed during travel through the lung), the rate of flow of these red blood cells as they pass through the lung can be determined. This can be expressed in the following terms:

$$\text{Fick cardiac output (liters/min)} = \frac{\text{Oxygen consumption (mL/min)}}{A-V_{O_2} \times 1.36 \times \text{Hgb} \times 10}$$

where $A-V_{O_2}$ is the arterial-venous oxygen saturation difference, Hgb is the hemoglobin concentration (mg/dL), and the constant 1.36 is the oxygen-carrying capacity of hemoglobin (expressed in mL O_2 /g Hgb).

Measurements must be made in the steady state. Automated methods can accurately determine the oxygen content within the blood samples. Thus the greatest source of variability in measurement is oxygen consumption. In the original Fick determinations, expiratory gas samples were collected in a plastic bag during a specified period. By measuring the expiratory oxygen concentration and knowing the concentration of oxygen in room air, the quantity of oxygen consumed over time could be determined. Currently, measurement of the expired oxygen concentration is quantified by the use of a polarograph. This device can be connected to the patient by a plastic hood or by a mouthpiece and tubing.

The advantage of the Fick method is that it is the most accurate method in patients with low cardiac output and tricuspid

regurgitation. It is also independent of factors that affect curve shape and cause errors in thermodilution cardiac output (e.g., tricuspid regurgitation). The Fick method suffers primarily from difficulty obtaining accurate oxygen consumption measurements and an inability to obtain a steady state under certain conditions. Because the method assumes mean flow over time, it is not suitable during rapid changes in flow. Also, the patient cannot be receiving supplemental oxygen during collection of a blood sample. In patients with significant mitral or aortic regurgitation, Fick cardiac output should not be used.

Many laboratories use an "assumed" Fick method in which the oxygen consumption index is assumed on the basis of the patient's age, sex, and body surface area or an estimate is made (125 mL/m²) on the basis of body surface area. However, when assumed oxygen consumption rather than measured oxygen consumption is used, large errors can occur.³⁹

Angiographic Cardiac Output. Stroke volume is the quantity of blood ejected with each beat. End-diastolic volume is the maximum LV volume and occurs immediately before the onset of systole. It occurs directly after atrial contraction in patients in sinus rhythm. End-systolic volume is the minimum LV volume during the cardiac cycle. Angiographic stroke volume can be calculated by tracing the LV end-diastolic and end-systolic images. Calibration of the images with grids or LV phantoms is necessary to obtain accurate LV volumes. Angiographic cardiac output and stroke volume are derived from the following equations:

$$\text{Stroke volume} = \text{EDV} - \text{ESV}$$

$$\text{Cardiac output} = (\text{EDV} - \text{ESV}) \times \text{Heart rate}$$

where EDV is end-diastolic volume and ESV is end-systolic volume.

The inherent inaccuracies of calibrating angiographic volumes often make this method of measurement unreliable. In cases of valvular regurgitation or atrial fibrillation, angiographic cardiac output does not accurately measure true systemic output. However, angiographic cardiac output is preferred over Fick or thermodilution output for calculation of stenotic valve areas in patients with significant aortic or mitral regurgitation.

Determination of Vascular Resistance. Vascular resistance calculations are based on the hydraulic principles of fluid flow, in which resistance is defined as the ratio of the decrease in pressure between two points in a vascular segment and the blood flow through the segment. Although this straightforward analogy to Ohm's law represents an oversimplification of the complex behavior of pulsatile flow in dynamic and diverse vascular beds, calculation of vascular resistance based on these principles has proved to be of value in several clinical settings.

Determination of the resistance in a vascular bed requires measurement of the mean pressure of the proximal and distal ends of the vascular bed and accurate measurement of cardiac output. Vascular resistance (R) is usually defined in absolute units (dyne-sec • cm⁻⁵) and is defined as $R = \text{mean pressure gradient (dyne/cm}^2\text{)}/\text{mean flow (cm}^3\text{/sec)}$. Hybrid units (Wood units) are less often used.⁴⁰

Systemic vascular resistance (SVR) in absolute units is calculated with the following equation:

$$\text{SVR} = \frac{80(Ao_m - RA_m)}{Q_s}$$

where Ao_m and RA_m are the mean pressure (in mm Hg) in the aorta and right atrium, respectively, and Q_s is systemic cardiac output (in liters/min). The constant 80 is used to convert units from mm Hg/liter/min (Wood units) to the absolute resistance units dyne-sec • cm⁻⁵.

PVR is derived from the following equation:

$$\text{PVR} = \frac{80(PA_m - LA_m)}{Q_p}$$

where PA_m and LA_m are mean pulmonary artery and left atrial pressure, respectively, and Q_p is PBF. If mean left atrial pressure has not been measured directly, mean pulmonary capillary wedge pressure is commonly substituted for it, although errors can occur because of this substitution. In the absence of an intracardiac shunt, Q_p is equal to systemic cardiac output. PVR describes the pressure across the major pulmonary vessels and the precapillary arterioles and pulmonary

capillary circulation. It is a more accurate assessment of the severity of pulmonary vascular disease than total pulmonary resistance is.

However, if left atrial or pulmonary capillary wedge pressure is not known, the term LA_m can be dropped from the numerator, and the resulting value is called total pulmonary resistance (TPR):

$$TPR = \frac{80(PA_m)}{Q_p}$$

This calculation is not often used because it neglects LV diastolic pressure. It is reserved for circumstances when measurement of left atrial or pulmonary capillary wedge pressure is not obtained.

Normal values are listed in Table 19-3.

Elevated resistance in the systemic and pulmonary circuits may represent reversible abnormalities or may be permanent because of irreversible anatomic changes. In several clinical situations, such as congestive heart failure, valvular heart disease, primary pulmonary hypertension, and congenital heart disease with intracardiac shunting, determination of whether elevated SVR or PVR can be lowered transiently in the catheterization laboratory may provide important insight into potential management strategies. Interventions that can be used in the laboratory include administration of vasodilating drugs (e.g., sodium nitroprusside), exercise, and (in patients with pulmonary hypertension) nitric oxide inhalation or intravenous epoprostenol, a pulmonary and systemic vasodilator (see Chapter 74).

Vascular impedance measurements account for blood viscosity, pulsatile flow, reflected waves, and arterial compliance. Hence vascular impedance has the potential to describe the dynamic relationship between pressure and flow more comprehensively than is possible with the simpler calculations of vascular resistance. However, because the simultaneous pressure and flow data required for the calculation of impedance are complex and difficult to obtain, the concept of impedance has failed to gain widespread acceptance, and vascular impedance has not been adopted as a routine clinical index.

Evaluation of Valvular Stenosis

Determination of the severity of valvular stenosis on the basis of the pressure gradient and flow across the valve is one of the most important aspects of the evaluation of patients with valvular heart disease (see Chapter 63). In many patients the magnitude of the pressure gradient alone is sufficient to distinguish clinically significant from insignificant valvular stenosis.

Determination of Pressure Gradients

Aortic Stenosis

In patients with aortic stenosis, the transvalvular pressure gradient is best measured with a micromanometer catheter and simultaneous recordings in the left ventricle and supravalvular aorta. A dual-lumen pigtail catheter is the most commonly used and preferred catheter that can accurately measure the aortic transvalvular gradient.

Although it is convenient to measure the gradient between the left ventricle and the femoral artery through the sheath, downstream augmentation of the pressure signal and delay in transmission of pressure between the proximal aorta and femoral artery may alter the pressure waveform substantially and introduce errors into the measured gradient. The LV–femoral arterial pressure gradient may not always be relied on in the calculation of valve orifice area in patients with moderate valve gradients. If the side port of the arterial introducing sheath is used to monitor femoral pressure, the inner diameter of the sheath should be at least 1F larger than the outer diameter of the LV catheter. A careful single catheter pull-back from the left ventricle to the aorta can be preferable to simultaneous measurement of LV and femoral artery pressure.

A single catheter with a distal and a proximal lumen or a micromanometer catheter with distal and proximal transducers is the best method for simultaneous measurement of LV and central aortic pressure.

The mean pressure gradient across the aortic valve is determined by planimetry of the area separating the LV and aortic pressure during multiple beats (Fig. 19-13), and it is this gradient that is applied to calculation of the valve orifice area. The peak-to-peak gradient, measured as the difference between peak LV pressure and

FIGURE 19-13 Various methods of describing an aortic transvalvular gradient. The peak-to-peak gradient (47 mm Hg) is the difference between maximal pressure in the aorta (Ao) and maximal pressure in the left ventricle (LV). The peak instantaneous gradient (100 mm Hg) is the maximal pressure difference between the Ao and LV when the pressures are measured at the same moment (usually during early systole). The mean gradient (green shaded area) is the integral of the pressure difference between the LV and Ao during systole (60 mm Hg). (From Bashore TM: *Invasive Cardiology: Principles and Techniques*. Philadelphia, BC Decker, 1990.)

peak aortic pressure, is commonly used to quantify the valve gradient because this measurement can be obtained rapidly and estimated visually. However, there is no physiologic basis for the peak-to-peak gradient because the maximum LV and aortic pressures rarely occur simultaneously. The peak-to-peak gradient measured in the catheterization laboratory is generally lower than the peak instantaneous gradient measured in the echocardiography laboratory because the peak instantaneous gradient represents the maximum difference in pressure between the left ventricle and aorta when pressures are measured simultaneously. This maximum pressure difference occurs on the upslope of the aortic pressure tracing (Fig. 19-13). The mean aortic transvalvular gradient and aortic valve area are well correlated with both techniques.⁴¹ In patients with low-gradient low-output aortic stenosis, pharmacologic maneuvers can be helpful (see the section *Physiologic and Pharmacologic Maneuvers*).

Mitral Stenosis

In patients with mitral stenosis, the most accurate means of determining the mitral valve gradient is direct measurement of left atrial pressure by the transseptal technique with simultaneous measurement of LV pressure and planimetry of the area bounded by the LV and left atrial pressure in diastole during several cardiac cycles (Fig. 19-14). Pulmonary capillary wedge pressure is usually substituted for left atrial pressure because it is more readily obtained. The pulmonary wedge pressure tracing must be realigned with the LV tracing for accurate determination of the mean gradient. Although it has generally been accepted that pulmonary capillary wedge pressure is a satisfactory estimate of left atrial pressure, studies indicate that pulmonary wedge pressure may systematically overestimate left atrial pressure by 2 to 3 mm Hg, thereby increasing the measured mitral valve gradient. Improperly wedged catheters resulting in damped pulmonary artery pressure recordings further overestimate the severity of mitral stenosis. If accurate positioning of the catheter in the wedge position is in doubt, the position can be confirmed by slow withdrawal of blood for oximetric analysis. Oxygen saturation equal to that in the systemic circulation confirms the wedge position.

Right-Sided Valvular Stenosis

In pulmonic stenosis, the valve gradient is obtained by catheter pull-back from the pulmonary artery to the right ventricle or by placement of separate catheters in the right ventricle and pulmonary artery. Multilumen catheters can also be used for simultaneous pressure

FIGURE 19-14 Pressure gradient in a patient with mitral stenosis. Pressure in the left atrium (LA) exceeds pressure in the left ventricle (LV) during diastole, thereby producing a diastolic pressure gradient (green shaded area). (From Bashore TM: *Invasive Cardiology: Principles and Techniques*. Philadelphia, BC Decker, 1990.)

recordings. Tricuspid valve gradients should be assessed with simultaneous recording of right atrial and RV pressure.

Calculation of Stenotic Valve Orifice Areas

The stenotic orifice area is determined from the pressure gradient and cardiac output with the formula developed by Gorlin and Gorlin, which involves the fundamental hydraulic relationships linking the area of an orifice to the flow and pressure drop across the orifice. Flow (F) and orifice area (A) are related by the fundamental formula

$$F = cAV$$

where V is velocity of flow and c is a constant accounting for central streaming of fluid through an orifice, which tends to reduce the effective orifice size. Hence,

$$A = F/cV$$

Velocity is related to the pressure gradient through the relationship $V = k(2g\Delta P)^{1/2}$, where k is a constant accounting for frictional energy loss, g is acceleration as a result of gravity (980 cm/sec^2), and ΔP is the mean pressure gradient (mm Hg). Substituting for V in the orifice area equation and combining c and k into one constant C ,

$$A = \frac{F}{44.3C\sqrt{\Delta P}}$$

Gorlin and Gorlin determined the value of the constant C by comparing the calculated valve area with actual valve area measured at autopsy or at surgery in 11 mitral valves. The maximal discrepancy between the actual mitral valve area and calculated values was just 0.2 cm^2 when the constant 0.85 was used. No data were obtained for

aortic valves, a limitation noted by the Gorlins, and a constant of 1.0 was assumed.

Because flow across the aortic valve occurs only during systole, the flow value for calculating aortic valve area is cardiac output in milliliters per minute divided by the systolic ejection period (SEP) in seconds per beat times the heart rate (HR) in beats per minute. The SEP is defined from aortic valve opening to closure. Hence aortic valve area (AVA) is calculated from the Gorlin formula by the following equation:

$$AVA (\text{cm}^2) = \frac{\text{Cardiac output (liters/min)} \times 1000}{(44.3)(\text{HR})(\text{SEP})\sqrt{\text{Mean gradient}}}$$

Similarly, because mitral flow occurs only during diastole, cardiac output is corrected for the diastolic filling period (DFP) in seconds per beat in the equation for mitral valve area (MVA), where the diastolic filling period is defined from mitral valve opening to mitral valve closure:

$$MVA (\text{cm}^2) = \frac{\text{Cardiac output (liters/min)} \times 1000}{(37.7)(\text{HR})(\text{DFP})\sqrt{\text{Mean gradient}}}$$

The normal aortic valve area is 2.6 to 3.5 cm^2 in adults. Valve areas less than 1.0 cm^2 represent severe aortic stenosis (see Chapter 63). The normal mitral valve area is 4 to 6 cm^2 , and severe mitral stenosis is present with valve areas smaller than 1.0 cm^2 .

The calculated valve area is often crucial in management decisions for patients with aortic stenosis or mitral stenosis. Hence it is essential that accurate and simultaneous pressure gradient and cardiac output determinations be made, especially in patients with borderline or low-pressure gradients.

The Gorlin-derived orifice area has limitations. Because the square root of the mean gradient is used in the Gorlin formula, the valve area calculation is more strongly influenced by cardiac output than by the pressure gradient. Thus errors in measuring cardiac output may have profound effects on the calculated valve area, particularly in patients with low cardiac output, in whom the calculated valve area is often of greatest importance.

As noted previously, the thermodilution technique may provide inaccurate cardiac output data when cardiac output is reduced or when concomitant aortic, mitral, or tricuspid regurgitation is present. Thus the Fick method of determining cardiac output is most accurate in assessing cardiac output, especially in low-output states. In patients with mixed valvular disease (stenosis and regurgitation) of the same valve, the use of forward flow as determined by the Fick method or thermodilution technique overestimates the severity of the valvular stenosis. This overestimation is due to the fact that the Gorlin formula depends on total forward flow across the stenotic valve, not net forward flow. If valvular regurgitation is present, angiographic cardiac output is the most appropriate measure of flow. If both aortic and mitral regurgitation are present, flow across a single valve cannot be determined, and neither aortic valve area nor mitral valve area can be assessed accurately.

Other potential errors and limitations also inherent with use of the Gorlin formula are related both to inaccuracies in measurement of valve gradients and to more fundamental issues regarding the validity of the assumptions underlying the formula. In low-output states, the Gorlin formula may systematically predict smaller valve areas than are actually present. Several lines of evidence indicate that the aortic valve area from the Gorlin formula increases with increases in cardiac output. Although this may represent an actual greater opening of stenotic valves by the higher proximal opening pressures that result from increases in transvalvular flow, the dependence of the calculated valve area on flow may also reflect inherent errors in the assumptions underlying the Gorlin formula, particularly with respect to the aortic valve.

The increase in Gorlin valve area with increases in transvalvular flow is not associated with alterations in direct planimetry of the

aortic valve area by transesophageal echocardiography. This phenomenon suggests that flow-related variation in the Gorlin aortic valve area is due to disproportional dependence of the formula on flow and not a true change in valve area.^{42,43}

An alternative simplified formula to determine valve areas has been proposed. The effects of the systolic ejection period and the diastolic filling period are relatively constant at normal heart rates, and these terms can be eliminated from the equation. This assumes that $(44.3 \times \text{HR} \times \text{SEP})$ is approximately equal to 1000 in most circumstances. In this modified approach, aortic valve area can be quickly estimated from the following formula:

$$\text{AVA (cm}^2\text{)} = \frac{\text{Cardiac output (liters/min)}}{\sqrt{\text{Peak-to-peak or mean gradient (mm Hg)}}}$$

Use of either the mean aortic transvalvular gradient or the peak-to-peak gradient produces similar correlation with the Gorlin formula.

Patients with low-output, low-gradient aortic stenosis remain a challenge in accurately determining valve area by either cardiac catheterization or echocardiography (see Chapters 14 and 63). Whether afterload mismatch or intrinsic contractility dysfunction is the primary problem in LV impairment can be difficult to ascertain. Thus the use of pharmacologic stress with low-dose dobutamine infusion has been advocated to distinguish moderate from severe aortic stenosis.⁴⁴⁻⁴⁹ The concept is that patients without true anatomic severe aortic stenosis will have an increase in valve areas with little change in transvalvular gradient.¹ If dobutamine increases aortic valve area more than 0.2 cm² with no change in gradient, it is likely that the baseline evaluation overestimated the severity of the aortic stenosis.¹ It has also been shown that patients whose stroke volume increases by less than 20% lack contractile reserve and have a poor prognosis with either medical or surgical therapy.⁴⁸ Despite theoretical limitations, the Gorlin formula has proved to be a reliable clinical determination for evaluation of patients with suspected aortic stenosis.

Measurement of Intraventricular Pressure Gradients

Demonstration of an intracavitary pressure gradient is among the most interesting yet challenging aspects of diagnostic catheterization (see Chapter 66). Simultaneous pressure measurements are obtained in either the central aorta or femoral artery and from within the LV cavity. Pull-back of a multipurpose end-hole catheter from the LV apex to a posterior position just beneath the aortic valve is used to demonstrate an intracavitary gradient. An erroneous intracavitary gradient may be seen if the catheter becomes entrapped by the hypertrophic myocardium.

The intracavitary gradient is distinguished from aortic valvular stenosis by loss of the aortic-LV gradient when the catheter is still within the left ventricle yet proximal to the myocardial obstruction. In addition, careful analysis of the upstroke of the aortic pressure waveform distinguishes valvular from subvalvular stenosis, with the aortic pressure waveform demonstrating slow upstroke in aortic stenosis. Other methods for localizing intracavitary gradients include the use of a dual-lumen catheter, use of a double-sensor micro-manometer catheter, or placement of an end-hole catheter in the LV outflow tract while a transseptal catheter is advanced into the left ventricle, with pressure being measured simultaneously. An intracavitary gradient may be increased by various provocative maneuvers, including the Valsalva maneuver, inhalation of amyl nitrate, introduction of a premature ventricular beat, or dobutamine infusion (see *Physiologic and Pharmacologic Maneuvers*).

Assessment of Valvular Regurgitation

The severity of valvular regurgitation is generally graded by visual assessment, although calculation of the regurgitant fraction is used occasionally. According to ACC/AHA guidelines, hemodynamic evaluation of either aortic or mitral regurgitant lesions is recommended as a class I indication when pulmonary artery pressure is disproportionate

to the severity of regurgitation assessed noninvasively or when a discrepancy is noted between clinical and noninvasive findings.¹ Exercise with right-heart hemodynamic assessment, including pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac output, may also provide useful information.

Visual Assessment of Regurgitation. Valvular regurgitation may be assessed visually by determination of the relative amount of radiographic contrast medium that opacifies the chamber proximal to its injection. Estimation of regurgitation depends on the volume of regurgitant, as well as on the size and contractility of the proximal chamber. The original classification scheme devised by Sellers and colleagues remains the standard in most catheterization laboratories:

+	Minimal regurgitant jet seen. Clears rapidly from the proximal chamber with each beat.
++	Moderate opacification of the proximal chamber and clearing with subsequent beats.
+++	Intense opacification of the proximal chamber that becomes equal to that of the distal chamber.
++++	Intense opacification of the proximal chamber that becomes more dense than that of the distal chamber. Opacification often persists over the entire series of images obtained.

Regurgitant Fraction. A gross estimate of the degree of valvular regurgitation may be obtained by determination of the regurgitant fraction (RF). The difference between angiographic stroke volume and forward stroke volume can be defined as the regurgitant stroke volume.

$$\text{Regurgitant stroke volume} = \text{Angiographic stroke volume} - \text{Forward stroke volume}$$

The RF is the portion of the angiographic stroke volume that does not contribute to net cardiac output. Forward stroke volume is the cardiac output determined by the Fick or thermodilution method divided by the heart rate. Thermodilution cardiac output cannot be used if significant concomitant tricuspid regurgitation is present.

When compared with visual interpretation, 1+ regurgitation is roughly equivalent to an RF of 20% or less, 2+ to an RF of 21% to 40%, 3+ to an RF of 41% to 60%, and 4+ to an RF of greater than 60%.

The assumption underlying determination of the RF is that angiographic cardiac output and forward cardiac output are accurate and comparable, a state requiring similar heart rates, stable hemodynamic states between measurements, and only a single regurgitant valve. Given these conditions, the equation yields only a gross approximation of regurgitant flow.

Shunt Determinations

Normally, PBF and SBF are equal. With abnormal communication between intracardiac chambers or great vessels, blood flow is shunted from the systemic circulation to the pulmonary circulation (left-to-right shunt), from the pulmonary circulation to the systemic circulation (right-to-left shunt), or in both directions (bidirectional shunt). The most commonly used method for shunt determination in the cardiac catheterization laboratory is the oximetric method. Although many shunts are suspected before cardiac catheterization, physicians performing the procedure should be vigilant in determining the cause of unexpected findings. For example, an unexplained pulmonary artery oxygen saturation exceeding 80% should raise the operator's suspicion for a left-to-right shunt, whereas unexplained arterial desaturation (<93%) may indicate a right-to-left shunt.⁵⁰ Arterial desaturation commonly results from alveolar hypoventilation and associated "physiologic shunting," causes of which include oversedation from premedication, pulmonary disease, pulmonary venous congestion, pulmonary edema, and cardiogenic shock. If arterial desaturation persists after the patient takes several deep breaths or after administration of 100% oxygen, a right-to-left shunt is likely.

Oximetric Method

The oximetric method is based on blood sampling from various cardiac chambers for determination of oxygen saturation. A

left-to-right shunt is detected when a significant increase in blood oxygen saturation is found between two right-sided vessels or chambers.

A screening oxygen saturation measurement for any left-to-right shunt is often performed with right-heart catheterization by sampling of blood in the SVC and the pulmonary artery. If the difference in oxygen saturation between these samples is 8% or greater, a left-to-right shunt may be present, and an oximetry “run” should be performed. This run obtains blood samples from all right-sided locations, including the SVC, IVC, right atrium, right ventricle, and pulmonary artery. In cases of interatrial or interventricular shunts, it is recommended that multiple samples be obtained from the high, middle, and low right atrium or the RV inflow tract, apex, and outflow tract to localize the level of the shunt. One may miss a small left-to-right shunt if the right atrium is used for screening purposes rather than the SVC because of incomplete mixing of blood in the right atrium, which receives blood from the IVC, SVC, and coronary sinus. Oxygen saturation in the IVC is higher than in the SVC because the kidneys have lower oxygen extraction relative to their blood flow than other organs do. In contrast, coronary sinus blood has higher oxygen extraction and subsequently very low oxygen saturation. Mixed venous saturation is most accurately measured in the pulmonary artery after complete mixing has occurred or can be calculated by IVC plus SVC samples (see [Shunt Quantification](#)).

A full saturation run obtains samples from the high and low IVC; high and low SVC; high, middle, and low right atrium; RV inflow and outflow tracts and midcavity; main pulmonary artery; left or right pulmonary artery; pulmonary vein and left atrium, if possible; left ventricle; and distal aorta. When a right-to-left shunt must be localized, samples for determination of oxygen saturation must be taken from the pulmonary veins, left atrium, left ventricle, and aorta. Although the major weakness of the oxygen step-up method is its lack of sensitivity, clinically significant shunts are generally detected by this technique. Obtaining multiple samples from each chamber can improve sampling error and variability. Another method of oximetric determination of intracardiac shunts uses a balloon-tipped fiberoptic catheter that allows continuous registration of oxygen saturation as the catheter is withdrawn from the pulmonary artery through the right-heart chambers into the SVC and IVC.

Shunt Quantification

The principles used to determine Fick cardiac output are also used to quantify intracardiac shunts. To determine the size of a left-to-right shunt, PBF and SBF determinations are required. PBF is simply oxygen consumption divided by the difference in oxygen content across the pulmonary bed, whereas SBF is oxygen consumption divided by the difference in oxygen content across the systemic bed. Effective blood flow (EBF) is the fraction of mixed venous return received by the lungs without contamination by shunt flow. In the absence of a shunt, PBF, SBF, and EBF are all equal. These equations are as follows:

$$\text{PBF} = \frac{\text{O}_2 \text{ consumption (mL/min)}}{(\text{PvO}_2 - \text{PaO}_2)}$$

$$\text{SBF} = \frac{\text{O}_2 \text{ consumption (mL/min)}}{(\text{SaO}_2 - \text{MvO}_2)}$$

$$\text{EBF} = \frac{\text{O}_2 \text{ consumption (mL/min)}}{(\text{PvO}_2 - \text{MvO}_2)}$$

where PvO_2 , PaO_2 , SaO_2 , and MvO_2 are the oxygen content (in milliliters of oxygen per liter of blood) of pulmonary venous, pulmonary arterial, systemic arterial, and mixed venous blood, respectively. Oxygen content is determined as outlined in the section on Fick cardiac output.

If a pulmonary vein is not sampled, systemic arterial oxygen saturation may be substituted, assuming that it is 95% or greater. As discussed earlier, if systemic arterial saturation is less than 93%, a

right-to-left shunt may be present. If arterial desaturation is present but not secondary to a right-to-left shunt, systemic arterial oxygen content is used. If a right-to-left shunt is present, pulmonary venous oxygen content is calculated as 98% of the oxygen capacity.

The mixed venous oxygen content is the average oxygen content of blood in the chamber proximal to the shunt. When assessing a left-to-right shunt at the level of the right atrium, one must calculate the mixed venous oxygen content on the basis of the contributing blood flow from the IVC, SVC, and coronary sinus. The most commonly used method is the Flamm formula:

$$\text{MvO}_2 = \frac{3 (\text{SVC O}_2 \text{ content}) + 1 (\text{IVC O}_2 \text{ content})}{4}$$

Assuming conservation of mass, the size of a left-to-right shunt, when no associated right-to-left shunt is present, is simply

$$\text{L} \rightarrow \text{R shunt} = \text{PBF} - \text{SBF}$$

When there is evidence of a right-to-left shunt in addition to a left-to-right shunt (also referred to as a bidirectional shunt), the approximate size of the left-to-right shunt is

$$\text{L} \rightarrow \text{R shunt} = \text{PBF} - \text{EBF}$$

and the approximate size of the right-to-left shunt is

$$\text{R} \rightarrow \text{L shunt} = \text{SBF} - \text{EBF}$$

The flow ratio PBF/SBF (or Q_p/Q_s) is used clinically to determine the significance of the shunt. A ratio of less than 1.5 indicates a small left-to-right shunt and a ratio of 1.5 to 2.0, a moderate-sized shunt. A ratio of 2.0 or higher indicates a large left-to-right shunt and generally requires percutaneous or surgical repair to prevent future cardiac complications. A flow ratio of less than 1.0 indicates a net right-to-left shunt. If oxygen consumption is not measured, the PBF/SBF ratio may be calculated as follows:

$$Q_p/Q_s = \text{PBF}/\text{SBF} = \frac{\text{SaO}_2 - \text{MvO}_2}{\text{PvO}_2 - \text{PaO}_2}$$

where SaO_2 , MvO_2 , PvO_2 , and PaO_2 are systemic arterial, mixed venous, pulmonary venous, and pulmonary arterial blood oxygen saturation, respectively.

PHYSIOLOGIC AND PHARMACOLOGIC MANEUVERS

Potentially significant cardiac abnormalities may be absent in the resting condition but might be unmasked by stress. Therefore, if the physician performing a cardiac catheterization procedure cannot elucidate the cause of a patient's symptoms at rest, various physiologic and pharmacologic maneuvers can be considered.

Dynamic Exercise

Dynamic exercise in the catheterization laboratory is performed by supine bicycle ergometry or upright bicycle exercise. Treadmill exercise can be performed outside the catheterization laboratory by inserting a balloon flotation catheter through an antecubital or internal jugular vein to measure pulmonary artery and wedge pressure and cardiac output. The associated changes in heart rate, cardiac output, oxygen consumption, and intracardiac pressure are monitored at rest and during progressive stages of exercise. Normally, the increased oxygen requirements of exercise are met by a rise in cardiac output and an increase in oxygen extraction from arterial blood. Patients with cardiac dysfunction are unable to increase their cardiac output appropriately in response to exercise and must meet the demands of the exercising muscle groups by increasing extraction of oxygen from arterial blood, thereby increasing the arteriovenous oxygen difference. The relationship between cardiac output and oxygen consumption is linear, and a regression formula can be used to calculate the predicted cardiac index at a given level of oxygen consumption. The actual cardiac index

divided by the predicted cardiac index is defined as the exercise index (see Chapter 13). A value of 0.8 or higher indicates a normal cardiac output response to exercise. The exercise factor is another method of describing the same relationship between cardiac output and oxygen consumption. The exercise factor is the increase in cardiac output divided by the increase in oxygen consumption. Normally, for every 100-mL/min increase in oxygen consumption with exercise, cardiac output should increase by at least 600 mL/min. Therefore a normal exercise factor should be 6 or higher.⁵¹

Supine exercise usually causes a rise in mean systemic and pulmonary arterial pressure. There is a proportionately greater decrease in SVR than in PVR and an increase in heart rate. Myocardial contractility increases as a result of both increased sympathetic tone and the increase in heart rate. The LV ejection fraction rises. During early levels of exercise, increased venous return augments LV end-diastolic volume, thereby leading to an increase in stroke volume. At progressively higher levels of exercise, both LV end-systolic volume and LV end-diastolic volume decrease such that the rise in stroke volume is negligible. Thus the augmentation in cardiac output during peak exercise in the catheterization laboratory is generally caused by an increase in heart rate. For this reason, use of agents that may impair the chronotropic response should be discontinued before catheterization if exercise is contemplated during the procedure.

Exercise may provoke symptoms in a patient who had been found to have valvular disease of borderline significance in the resting state (see Chapter 63). Exercise increases the transvalvular mitral gradient and pulmonary artery pressure in mitral stenosis.

The hemodynamic response to exercise is also useful in evaluating regurgitant valvular lesions. Clinically important valvular regurgitation exists if an increase occurs in LV end-diastolic pressure, pulmonary capillary wedge pressure, and SVR in conjunction with a reduced exercise index (<0.8) and abnormal exercise factor (<0.6). Simultaneous echocardiographic evaluation of valvular regurgitation is also useful in equivocal cases. Patients with myocardial disease, ischemic or otherwise, may have pronounced increases in LV end-diastolic pressure with exercise.

Pacing Tachycardia

Rapid atrial or RV pacing increases myocardial oxygen consumption and myocardial blood flow. With pacing, in contradistinction to dynamic exercise, LV end-diastolic volume decreases, and there is little change in cardiac output. This method may be used to determine the significance of coronary artery disease or valvular abnormalities. For example, the gradient across the mitral valve increases with rapid atrial pacing because of the increase in heart rate. Pacing has the advantage of allowing greater control and rapid termination of the induced stress.

Physiologic Stress

Various physiologic stresses alter the severity of obstruction in patients with hypertrophic cardiomyopathy (see Chapter 66). The Valsalva maneuver (forcible expiration against a closed glottis) increases the systolic LV outflow tract pressure gradient in the strain phase, during which there is a decrease in venous return and decreased LV volume. This maneuver is also abnormal in patients with congestive heart failure. Another useful maneuver in patients with hypertrophic obstructive cardiomyopathy is the introduction of a premature ventricular beat (Brockenbrough maneuver). Premature ventricular contractions normally increase the pulse pressure of the subsequent ventricular beat. In obstructive hypertrophic cardiomyopathy, the outflow gradient is increased during the post-premature beat along with a decrease in the pulse pressure of the aortic contour after the beat. A premature ventricular beat may also accentuate the spike-and-dome configuration of the aortic pressure waveform.

Rapid volume loading may reveal occult pericardial constriction (see Chapter 71), when atrial and ventricular filling pressures are relatively normal under baseline conditions as a result of hypovolemia, and can help distinguish pericardial constriction from myocardial restriction. The Kussmaul sign occurs in pericardial constriction. With inspiration it is demonstrated when mean right atrial pressure fails to decrease or actually increases in relation to impaired RV filling. The RV to LV systolic pressure–time area ratio during inspiration versus expiration is called the systolic area index. This is a measure of enhanced ventricular interdependence^{52,53} (Fig. 19-15). The index is significantly higher in those with proven constrictive pericarditis than in those with restrictive cardiomyopathy (1.4 ± 0.2 versus 0.92 ± 0.019 ; $P < 0.0001$), with a sensitivity of 97% and predicted accuracy of 100% for identification of constriction.

FIGURE 19-15 LV and RV high-fidelity manometer pressure traces from two patients during expiration and inspiration. Both patients have early rapid filling and elevation and end-equalization of LV and RV pressure at end-expiration. **A**, Patient with surgically documented constrictive pericarditis. During inspiration there is an increase in the area of the RV pressure curve (pink shaded area) relative to expiration. The area of the LV pressure curve (green shaded area) decreases during inspiration in comparison to expiration. **B**, Patient with restrictive myocardial disease documented by endomyocardial biopsy. During inspiration there is a decrease in the area of the RV pressure curve (pink shaded area) relative to expiration. The area of the LV pressure curve (green shaded area) is unchanged during inspiration in comparison to expiration.

Pharmacologic Maneuvers

Dobutamine infusion during cardiac catheterization is indicated in patients with low-flow, low-gradient aortic stenosis (see Chapters 14 and 63).^{1,49} In patients with a mean gradient below 30 mm Hg, low cardiac output, and low ejection fraction ($<40\%$), the Gorlin formula may not reflect the true valve area. Provocation with dobutamine infusion can assist in distinguishing intrinsic contractile dysfunction from afterload mismatch as a result of valvular stenosis. Up to a third of patients with low-output severe aortic stenosis as calculated by the Gorlin formula may have pseudosevere aortic stenosis.⁵⁴

Resting hemodynamics, including the transvalvular gradient, cardiac output, and aortic valve area, should be determined. Dobutamine is infused at 5 $\mu\text{g/kg/min}$ and increased by 3 to 10 $\mu\text{g/kg/min}$ every 5 minutes to a maximum of 40 $\mu\text{g/kg/min}$, mean gradient above 40 mm Hg, 50% increase in cardiac output, or heart rate higher than 140 beats/min. Patients with a final aortic valve area smaller than 1.2 cm^2 and mean gradient higher than 30 mm Hg are considered to have severe aortic stenosis.⁴⁴⁻⁴⁷

Nitric oxide is an endothelium-derived vasodilator with selective pulmonary vasodilator properties that is useful in evaluating patients with pulmonary hypertension (see Chapter 74). Inhaled nitric oxide is inactivated rapidly, in contrast to intravenous vasodilators, which can cause severe systemic hypotension.⁵⁵ It has been well established that lowering of pulmonary artery pressure with vasodilators predicts a favorable clinical outcome.

Inhaled nitric oxide can be used to safely and effectively assess the capacity of a patient for a pulmonary vasodilator response without causing systemic hypotension. It can accurately predict a response to subsequent medical therapy.^{56,57} Doses of 10, 20, 40, or 80 ppm can be tested during 5- to 10-minute intervals with serial sampling of blood for determination of mean pulmonary artery

pressure and calculation of PVR and cardiac output. The definition of an acute response that may warrant initiation of long-term therapy with oral calcium channel blockers is a decrease in mean pulmonary artery pressure of at least 10 mm Hg to an absolute mean pulmonary artery pressure of less than 40 mm Hg without a decrease in cardiac output.

Sodium nitroprusside infusion may improve cardiac output and filling pressure in patients with dilated cardiomyopathy and in those with mitral regurgitation by lowering SVR and PVR. A favorable response to sodium nitroprusside infusion may predict a good clinical outcome.

Agents that increase SVR, such as phenylephrine, reduce the gradient in obstructive hypertrophic cardiomyopathy. This can be used to improve acute systemic hypotension in patients with hypertrophic cardiomyopathy (see Chapter 66).

Isoproterenol infusion may be used to simulate supine dynamic exercise, although untoward side effects limit its applicability. This drug's positive inotropic and chronotropic effects can increase the gradient in patients with obstructive hypertrophic cardiomyopathy and mitral stenosis. Nitroglycerin and amyl nitrate decrease preload and accentuate the systolic gradient in patients with obstructive hypertrophic cardiomyopathy. Amyl nitrate is generally inhaled, and its onset and offset of action are rapid.

ADJUNCTIVE DIAGNOSTIC TECHNIQUES

Left Ventricular Electromechanical Mapping

Advances in catheter design and navigational technology have resulted in catheter-based three-dimensional mapping systems for

evaluation of regional and global LV function. The system provides simultaneous electrical, mechanical, and anatomic information.⁵⁸

Electromechanical LV maps can distinguish viable from nonviable myocardium and ischemic from nonischemic myocardium and correlate with thallium uptake.⁵⁹

The mapping system can predict recovery of function after revascularization by providing on-line assessment of viability.⁶⁰ This technique holds promise for guiding local delivery of myocardial regeneration therapies, such as stem cell injection.⁶¹

Intracardiac Echocardiography

Intracardiac echocardiography (ICE) is used for transvenous imaging within the cardiac chambers. It consists of an 8F or 10F, 90- or 110-cm catheter that permits two planes of bidirectional steering in the anterior-posterior and left-right direction. The transducer has variable frequencies of 5 to 10 MHz with multiple phased-array features, including two-dimensional imaging and color and spectral Doppler analysis.

ICE provides imaging of the interatrial or interventricular septum and left-sided heart structures from either the right atrium or ventricle, with penetration of up to 15 cm. Applications include guidance for percutaneous closure of atrial septal defects and patent foramen ovale, thus mitigating the need for transesophageal echocardiography and anesthesia (Fig. 19-16). In patients requiring transseptal puncture, ICE can facilitate localization of the fossa ovalis. ICE is also used to guide electrophysiologic procedures by identification of anatomic structures difficult to view with fluoroscopy (e.g., pulmonary veins or fossa ovalis for transseptal puncture).²⁸

FIGURE 19-16 A, ICE disposable transducer (Acuson, Inc.) with a steering apparatus on the proximal end and a flexible body with a transducer on the distal tip of the catheter. B, Tenting of the membranous fossa by the dilator-needle assembly. The transseptal needle assembly (arrowheads) is advanced to indent the fossa membrane. C, Advancement of the transseptal needle across the membranous fossa. Here the needle (arrowheads) is seen near the posterosuperior left atrial wall. The membrane remains tented because the dilator has not yet crossed the septum. D, Passage of the dilator and sheath across the interatrial septum. The dilator and sheath assembly has now advanced into the left atrium, thereby releasing the tenting of the membranous fossa. FO = fossa ovalis; LA = left atrium; RA = right atrium. (From Johnson SB, Seward JB, Packer DL: Phased-array intracardiac echocardiography for guiding transseptal catheter placement: Utility and learning curve. *Pacing Clin Electrophysiol* 25:402, 2002.)

TABLE 19-5 Diagnostic Catheterization–Related Complications in Patients Without ST-Elevation Myocardial Infarction (N = 1,091,557)

Complications (%)	
Any adverse event	1.35
Cardiogenic shock	0.24
Heart failure	0.38
Pericardial tamponade	0.03
Stroke	0.17
% of the total number of strokes that were hemorrhagic	9.16
New requirement for dialysis	0.14
In-hospital mortality	
Non-risk adjusted	0.72
Non-risk adjusted, excluding CABG patients	0.60
CABG performed during admission	7.47
CABG status	
Salvage/emergency	0.01/0.27
Urgent/elective	5.27/1.92
Bleeding Complications (%)	
Any bleeding event within 72 hr of the procedure	0.49
Any other vascular complication requiring treatment	0.15

COMPLICATIONS ASSOCIATED WITH CARDIAC CATHETERIZATION

Cardiac catheterization is a relatively safe procedure but has a well-defined risk for morbidity and mortality⁹ (Table 19-5). The potential risk for major complications during cardiac catheterization is often related to comorbid disease. The use of low-osmolar and isosmolar contrast media, lower-profile diagnostic catheters, and reduced anticoagulation, as well as extensive operator experience, has reduced the incidence of complications. Several large studies have provided insight into the incidence of major events and delineated cohorts of patients at increased risk.^{9,62,63}

Death related to diagnostic cardiac catheterization occurs in 0.08% to 0.75% of patients, depending on the population studied. Data from the Society for Cardiac Angiography identified subsets of patients with an increased mortality rate.⁶² In an analysis of 58,332 patients, multivariate predictors of significant complications were moribund status, advanced New York Heart Association functional class, hypotension, shock, aortic valve disease, renal insufficiency, unstable angina, mitral valve disease, acute myocardial infarction within 24 hours, congestive heart failure, and cardiomyopathy. The risk for any complication during cardiac catheterization is increased further in octogenarians. Although overall mortality is approximately 0.8% in this cohort, the risk for nonfatal major complications, which are primarily peripheral vascular, is approximately 5%.

Risk for myocardial infarction varies from 0.03% to 0.06%, risk for significant bradyarrhythmias or tachyarrhythmias varies from 0.56% to 1.3%,⁶² and risk for neurologic complications varies from 0.03% to 0.2%.^{64,65} One study using serial cranial magnetic resonance imaging demonstrated a 22% incidence of focal acute cerebral embolic events after retrograde crossing of stenotic aortic valves, and 3% of patients demonstrated clinically apparent neurologic deficits.⁶⁴ However, this study is in contradistinction to previously published large clinical series and requires additional validation.

Stroke can occur periprocedurally in the laboratory or within a few hours after the procedure. Whether the mechanism is different is unclear. Stroke should be distinguished from other conditions, including seizure, migraine, hypoglycemia, and encephalopathy. Standard stroke management with a multidisciplinary team is

important to improve prognosis. Predictors of stroke include diabetes mellitus, hypertension, previous stroke, and renal failure. Procedure length, volume of contrast material, urgent indications, and use of IABPs are known to increase the risk for stroke.⁶⁵

The most common complication is bleeding at the arterial access site, which is usually manifested by minor oozing or small hematomas. The incidence of major vascular complications in most series has suggested a slightly higher frequency when the Sones brachial approach is used. The incidence of major vascular complications has decreased during the last decade and is currently reported to be approximately 0.20%.⁶³ Major vascular complications include occlusion requiring arterial repair or thrombectomy, retroperitoneal bleeding, hematoma formation, pseudoaneurysm, arteriovenous fistula formation, and infection. In a patient with unexplained hypotension or back pain, retroperitoneal hematoma should be suspected. Evaluation should include serial complete blood count determinations, evaluation of anticoagulation status, and either CT or ultrasound evaluation of the groin, pelvis, and abdomen. The risk of requiring surgical repair for vascular injury is related to advanced age, congestive heart failure, and larger body surface area. With ultrasound guidance, many pseudoaneurysms can be successfully treated percutaneously with directed infusion of thrombin, and surgical repair can often be avoided.

Proper management of the arterial sheath is important in avoiding complications. Because dwell times correlate with hematoma formation, all sheaths should be removed as soon as possible with an activated clotting time below 170. Frequent blood pressure and pulse monitoring is essential.

Systemic complications can vary from mild vasovagal responses to severe vagal reactions that lead to prolonged hypotension. Minor complications occur in approximately 4% of patients undergoing routine cardiac catheterization.⁶⁶ The most common untoward effects are transient hypotension and brief episodes of angina lasting less than 10 minutes.

Hives can occur but are less commonly observed with low-osmolar contrast agents and with intra-arterial administration. They are readily treated with intravenous corticosteroids and diphenhydramine. Rarely, anaphylactoid complications are observed. These are also treated with intravenous corticosteroid and diphenhydramine. Epinephrine is administered in severe reactions; a 0.1-mg/mL dilution is administered at 1.4 µg/min over a 5-minute period.

The most common complications of right-heart catheterization are nonsustained atrial and ventricular arrhythmias. Major complications associated with right-heart catheterization are infrequent but include pulmonary infarction, pulmonary artery or RV perforation, and infection.

FUTURE PERSPECTIVES

The expansion of transcatheter treatment of coronary, valvular, and structural heart disease has stimulated the growth of cardiac catheterization in conjunction with percutaneous therapeutic procedures (see Chapters 56 and 63). Transcatheter imaging and provocative testing expand the catheterization laboratory beyond conventional radiographic imaging and hemodynamic assessment. In-depth knowledge of the hemodynamics of valvular and structural heart disease is critical for proper use of transcatheter therapies.

High-resolution coronary CT angiography will probably replace the need for cardiac catheterization in low-risk patients in whom coronary artery disease can be excluded with noninvasive testing (see Chapter 18). The availability of multiple noninvasive screening modalities will enable detection of cardiovascular disease, with cardiac catheterization being used to precisely define the extent and severity of coronary and valvular heart disease.

APPROPRIATE USE CRITERIA

Diagnostic Cardiac Catheterization

Robert O. Bonow and Charles J. Davidson

The American College of Cardiology Foundation, the Society for Cardiovascular Angiography and Interventions, and other organizations

have published appropriate use criteria (AUC) for diagnostic cardiac catheterization in various clinical scenarios.¹ The AUC are intended to complement and to incorporate disease-based guideline recommendations, such as stable ischemic heart disease, heart failure, and valvular heart disease, as much as possible while acknowledging that many clinical scenarios faced by clinicians do not fit neatly into the evidence base from the published literature on which more formal guidelines are built. This approach has become the primary mechanism for rating noninvasive imaging procedures, including echocardiography, nuclear cardiology, cardiac magnetic resonance imaging, and cardiac computed tomography (see guidelines in Chapters 14G,

16G, 17G, and 18G), while guidelines continue to be developed for clinical disease states and syndromes.

After development of the clinical indications to be rated, a panel with a broad array of expertise (i.e., not just experts in catheterization and interventional cardiology) rated the “appropriateness” of diagnostic catheterization in each scenario by using the following definition: “An appropriate diagnostic cardiac catheterization (left heart, right heart, ventriculography, and/or coronary angiography) is one in which the expected incremental information combined with clinical judgment exceeds the negative consequences by a sufficiently wide margin for a specific indication that the procedure is generally considered acceptable care and a reasonable approach for the indication.”¹ Rating scores were made on a scale of 1 to 9, with a score of 9 indicating highly appropriate use of catheterization. Using an iterative modified Delphi exercise process with predefined rules, a final rating

score is established for each indication and grouped as A, score of 7 to 9, an appropriate test for the specific indication (the test is generally acceptable and is a reasonable approach for the indication); U, score of 4 to 6, uncertain for the specific indication (the test may be generally acceptable and may be a reasonable approach for the indication); and I, score of 1 to 3, an inappropriate test for that indication (the test is not generally acceptable and is not a reasonable approach for the indication) (**Table 19G-1**).¹

The updated AUC methodology in 2013² changed the AUC nomenclature such that the term “inappropriate” for ratings of 1 to 3 is now termed “rarely appropriate” and ratings of 4 to 6 are now termed “may be appropriate.” Ratings of 7 to 9 remain “appropriate.” The AUC for diagnostic catheterization¹ have not yet been updated to reflect this change in terminology. However, the recent AUC documents for multimodality imaging in stable ischemic heart disease and heart

TABLE 19G-1 Appropriate Use Criteria for Diagnostic Catheterization

Appropriate Use Score (1-9)				
Suspected or Known Acute Coronary Syndrome				
1	Cardiogenic shock due to suspected ACS	A (9)		
2	ST-segment elevation MI or suspected STEMI	A (9)		
		Risk Score (e.g., TIMI, GRACE)		
		Low	Intermediate	High
3	UA/NSTEMI	A (7)	A (8)	A (9)
4	Suspected ACS with newly diagnosed LV wall motion abnormality or newly diagnosed resting myocardial perfusion defect	A (7)	A (8)	A (9)
Suspected CAD: No Prior Noninvasive Stress Imaging (No Prior PCI, CABG, or Angiogram Showing ≥50% Angiographic Stenosis)				
Asymptomatic				
5	Low global CAD risk	I (1)		
6	Intermediate global CAD risk	I (3)		
7	High global CAD risk	U (4)		
Symptomatic				
8	Low pretest probability	I (3)		
9	Intermediate pretest probability	U (6)		
10	High pretest probability	A (7)		
Suspected CAD: Prior Noninvasive Testing (No Prior PCI, CABG, or Angiogram Showing ≥50% Angiographic Stenosis)				
		Pretest Symptom Status		
		Asymptomatic	Symptomatic	
ECG Stress Testing				
11	Low-risk findings (e.g., Duke Treadmill score ≥5)	I (1)		U (4)
12	Intermediate-risk findings (e.g., Duke score 4 to -10)	U (4)		U (6)
13	High-risk findings (e.g., Duke Treadmill score ≤ -11)	A (7)		A (8)
14	Other high-risk finding (ST segment elevation, hypotension with exercise, ventricular tachycardia, prolonged ST segment depression)	A (7)		A (9)
Stress Testing with Imaging (SPECT MPI, Stress Echocardiography, Stress PET, Stress CMR)				
15	Low-risk findings (e.g., <5% ischemic myocardium on stress SPECT MPI or stress PET, no stress- induced wall motion abnormalities on stress echo or stress CMR)	I (2)		U (4)
16	Intermediate-risk findings (e.g., 5-10% ischemic myocardium on stress SPECT MPI or stress PET, stress-induced wall motion abnormality in a single segment on stress echo or stress CMR)	U (4)		A (7)
17	High-risk findings (e.g., >10% ischemic myocardium on stress SPECT MPI or stress PET, stress-induced wall motion abnormality in two or more segments on stress echo or stress CMR)	A (7)		A (9)
18	Other high-risk finding (e.g., transient ischemic dilation (TID), significant stress-induced LV dysfunction)	A (7)		A (8)
19	Discordant findings (e.g., low- risk prior imaging with ongoing symptoms consistent with ischemic equivalent)	—		A (7)

Continued

OVERVIEW AND BACKGROUND

Coronary arteriography remains the standard for identifying the presence or absence of arterial narrowings related to atherosclerotic coronary artery disease (CAD) and provides the most reliable anatomic information for determining the appropriateness of medical therapy, percutaneous coronary intervention (PCI), or coronary artery bypass grafting (CABG) in patients with ischemic CAD. First performed by Mason Sones in 1959, coronary arteriography has subsequently become one of the most widely used invasive procedures in cardiovascular medicine.¹ It is performed by direct injection of radiopaque contrast material into the coronary arteries and recording high-resolution digital angiograms on exportable radiographic medium.

The methods used to perform coronary arteriography have improved substantially since 1959. Smaller (sizes 4F and 5F), high-flow injection catheters have replaced larger (8F) thick-walled ones, and the reduced sheath size has allowed same-day coronary arteriography, ambulation, and discharge. Complication rates have fallen as a result of a better understanding of the periprocedural management of patients undergoing cardiac catheterization. Transradial access has further reduced vascular complication rates and allows early ambulation after the procedure. Digital angiographic laboratories now permit high-quality image acquisition, electronic storage, and rapid image transfer and dissemination.

Almost 2 million patients will undergo coronary arteriography in the United States this year. Cardiac catheterization is available in more than 80% of U.S. hospitals, and approximately 20% of these centers also provide cardiac surgery services.² Although the number of patients undergoing coronary arteriography has plateaued in the United States, more routine cardiac catheterizations are being performed in the community setting, often without cardiac surgical services on site.²

This chapter reviews the indications, risks, techniques, and program oversight for coronary arteriography; the normal coronary anatomy and pathologic coronary variants; the qualitative and quantitative angiographic methods to assess severity of stenoses; and the potential technical pitfalls of coronary angiography for assessing the extent of CAD. This chapter also provides an overview of the current and evolving methods for intracoronary imaging.

INDICATIONS AND CONTRAINDICATIONS FOR CORONARY ARTERIOGRAPHY

Coronary arteriography establishes the presence or absence of coronary stenoses and aids in the determination of therapeutic options for revascularization. Its role as the initial diagnostic tool for determining prognosis in patients with suspected CAD has been challenged as a result of the relatively low rates of disease in patients without symptoms or suggestive findings on noninvasive studies.³ The 2012 Multi-Society Guidelines for the Diagnosis and Management of Patients with Stable Ischemic Heart Disease has provided recommendations for the use of coronary arteriography as a supplement to symptom status and noninvasive studies⁴ (Table 20-1). Furthermore, the Appropriate Use Criteria (AUC) Task Force has evaluated a number of clinically relevant scenarios for coronary angiography and revascularization.^{5,6} Based on the predominance of the evidence that includes (1) the clinical presentation (e.g., stable angina or an acute coronary syndrome), (2) the severity of angina, (3) the response to medical therapy, (4) magnitude of ischemia as determined by noninvasive testing, and (5) the extent of anatomic disease and its complexity, coronary revascularization is deemed “appropriate,” “may be appropriate,” or “rarely appropriate.”^{5,6} The AUC are used commonly in the cardiac catheterization laboratory to document indications for coronary arteriography and revascularization. The frequency of normal or insignificant CAD with diagnostic coronary arteriography ranges from 20% to 39%, depending on the types of patients studied (e.g., stable angina versus acute coronary syndrome).²

Coronary arteriography is increasingly performed in community-based cardiac catheterization laboratories without on-site cardiac surgery. Although the risk of adverse events associated with coronary arteriography is low at such centers, patients with pulmonary edema resulting from ischemia, patients with complex congenital disease, and pediatric patients should still be referred to centers with on-site surgery in the event that complications occur.² Minimal-volume criteria for cardiac catheterization are lacking; nevertheless, operators should be proficient in the performance of coronary arteriography and perform their procedures at hospitals that have established policies to ensure patient safety.⁷ A dedicated quality assurance program

is mandatory for all facilities that offer coronary arteriography, to ensure that the complication rates are not excessive.²

Chronic Stable Angina

Coronary arteriography is recommended as an initial diagnostic test for the evaluation of CAD in two settings: patients with stable ischemic heart disease who have survived sudden cardiac death or have

potentially lethal ventricular arrhythmias and patients who develop worsening symptoms of congestive heart failure when exercise testing is not feasible.⁴ In other patients with stable ischemic heart disease, noninvasive stress testing is recommended as the initial assessment tool for the detection of CAD (see Chapters 14 and 16).⁴ Coronary arteriography is recommended to assess risk when noninvasive testing indicates a high likelihood of ischemic heart disease and when the benefits are deemed to exceed the risks¹ (Table 20-2).

TABLE 20-1 Indications for Coronary Arteriography*

CLASS I	CLASS IIA	CLASS IIB	CLASS III
Stable Ischemic Coronary Artery Disease			
<ul style="list-style-type: none"> Patients with SIHD who have survived sudden cardiac death or potentially life-threatening ventricular arrhythmia should undergo coronary angiography to assess cardiac risk. (<i>Level of evidence: B</i>) Patients with SIHD who develop symptoms and signs of heart failure should be evaluated to determine whether coronary angiography should be performed for risk assessment. (<i>Level of evidence: B</i>) Coronary angiography is recommended for patients with SIHD whose clinical characteristics and results of noninvasive testing indicate a high likelihood of severe IHD and when the benefits are deemed to exceed risk. (<i>Level of evidence: C</i>) 	<ul style="list-style-type: none"> Coronary angiography is reasonable to further assess risk in patients with SIHD who have depressed LV function (EF <50%) and moderate risk criteria on noninvasive testing with demonstrable ischemia. (<i>Level of evidence: C</i>) Coronary angiography is reasonable to further assess risk in patients with SIHD and inconclusive prognostic information after noninvasive testing or in patients for whom noninvasive testing is contraindicated or inadequate. (<i>Level of evidence: C</i>) Coronary angiography for risk assessment is reasonable for patients with SIHD who have unsatisfactory quality of life from angina, have preserved LV function (EF >50%), and have intermediate risk criteria on noninvasive testing. (<i>Level of evidence: C</i>) 	<ul style="list-style-type: none"> None 	<ul style="list-style-type: none"> Coronary angiography for risk assessment is not recommended in patients with SIHD who elect not to undergo revascularization or who are not candidates for revascularization because of comorbidities or individual preferences. (<i>Level of evidence: B</i>) Coronary angiography is not recommended to further assess risk in patients with SIHD who have preserved LV function (EF >50%) and low-risk criteria on noninvasive testing. (<i>Level of evidence: B</i>) Coronary angiography is not recommended to assess risk in patients who are at low risk according to clinical criteria and who have not undergone noninvasive risk testing. (<i>Level of evidence: C</i>) Coronary angiography is not recommended to assess risk in asymptomatic patients with no evidence of ischemia on noninvasive testing. (<i>Level of evidence: C</i>)
Unstable Angina (UA) and Non-ST-Segment Elevation Myocardial Infarction (NSTEMI)			
<ul style="list-style-type: none"> An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in UA/NSTEMI patients who have refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures). (<i>Level of evidence: B</i>) An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is indicated in initially stabilized UA/NSTEMI patients (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events (<i>Level of evidence: A</i>) 	<ul style="list-style-type: none"> It is reasonable to choose an early invasive strategy (within 12 to 24 hours of admission) over a delayed invasive strategy for initially stabilized high-risk patients with UA/NSTEMI. For patients not at high risk, a delayed invasive approach also is reasonable. (<i>Level of evidence: B</i>) 	<ul style="list-style-type: none"> In initially stabilized patients, an initially conservative (i.e., selectively invasive) strategy may be considered as a treatment approach for UA/NSTEMI patients (without serious comorbidity or contraindications to such procedures) who have an elevated risk for clinical events, including those who are troponin-positive. (<i>Level of evidence: B</i>) The decision to implement an initial conservative (vs. initial invasive) strategy in these patients may be made by considering physician and patient preferences. (<i>Level of evidence: C</i>) 	<ul style="list-style-type: none"> An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with extensive comorbidities (e.g., liver or pulmonary failure, cancer), in whom the risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization. (<i>Level of evidence: C</i>) An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with acute chest pain and a low likelihood of ACS. (<i>Level of evidence: C</i>) Intervention for an early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) should not be performed in patients who will not consent to revascularization regardless of the findings. (<i>Level of evidence: C</i>)

TABLE 20-2 Risk Stratification in Patients with Stable Ischemic Coronary Artery Disease

High Risk (>3% annual risk of death or MI)
Severe resting LV dysfunction (LVEF <35%) not explained by noncoronary causes
Resting perfusion abnormalities ≥10% of the myocardium in patients without previous history of MI
Stress ECG findings including ≥2 mm ST depression at low workload or persisting into recovery, exercise-induced ST-segment elevation of exercise-induced VT/VF
Severe stress-induced LV dysfunction (peak exercise LVEF <45% or drop in LVEF with stress ≥10%)
Stress-induced perfusion abnormalities ≥10% of myocardium or stress segmental scores indicating multiple vascular territories with abnormalities
Stress-induced LV dilation
Inducible wall motion abnormality (involving >2 segments or 2 coronary beds)
Wall motion abnormality developing at low dose dobutamine (≥10 mg/kg/min) or at a low heart rate (<120 beats/min)
Coronary artery calcium >400 Agatston units
Multivessel obstructive CAD (≥70% stenosis) or left main stenosis (≥50% diameter stenosis) of CCTA
Intermediate Risk (1%-3% annual risk of death or MI)
Mild/moderate resting LV dysfunction (LVEF 35%-49%) not readily explained by noncoronary causes
Resting perfusion abnormalities in 5%-9.9% of the myocardium in patients without a history of previous evidence of MI
≥1 mm of ST segment depression occurring with exertional symptoms
Stress-induced perfusion abnormalities encumbering 5%-9.9% of the myocardium or stress segmental scores (in multiple segments) indicating one vascular territory with abnormalities but without LV dilation
Small wall motion abnormality involving 1 or 2 segments and only one coronary bed
Coronary artery calcium 100 to 299 Agatston units
One vessel CAD (≥70% stenosis) or moderate CAD stenosis (≥50% to 69% diameter stenosis) of CCTA in ≥2 vessels on CCTA
Low Risk (< 1% annual death or MI)
Low risk treadmill score (score ≥5) or no new ST-segment changes or exercise-induced chest pain symptoms with maximal levels of exercise
Normal or small myocardial perfusion defect at rest or with stress encumbering <5% of the myocardium
Normal stress or no change of limited resting wall motion abnormalities during stress
Coronary artery calcium <100 Agatston units
No coronary stenosis >50% on CCTA

CCTA = coronary CT angiography; ECG = electrocardiogram; LV = left ventricle; LVEF = left ventricular ejection fraction; MI = myocardial infarction; VT/VF = ventricular tachycardia/ventricular fibrillation.

Modified from Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACPIAATS/PCNA/SCAI/STS Guideline for the diagnosis and management of patients with stable ischemic heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 60:e44, 2012.

Coronary arteriography is a reasonable investigational strategy to further assess risk in patients with left ventricular (LV) dysfunction (i.e., LV ejection fraction <50%) in whom noninvasive testing yields evidence of ischemia, in those patients in whom such testing provides inconclusive evidence, or in patients for whom noninvasive testing is contraindicated or inadequate.⁴ Coronary arteriography also constitutes a reasonable assessment option in patients with stable ischemic heart disease who report an unsatisfactory quality of life because of angina, on a background of preservation of ventricular function, and in whom noninvasive testing reveals intermediate risk criteria.⁴

On the basis of studies that failed to show a reduction in death and myocardial infarction (MI) with PCI compared with maximal medical therapy,⁸ coronary arteriography is not recommended in patients with stable ischemic heart disease who are not candidates for revascularization because of comorbid conditions or personal preference. Coronary arteriography also is not recommended in patients with normal ventricular function and low-risk criteria on noninvasive testing, or those with low-risk criteria in the absence of noninvasive testing.⁴ Coronary arteriography is not recommended in asymptomatic patients with no evidence of ischemia on noninvasive testing.⁴ In the absence of symptoms and signs of ischemia, the presence of coronary calcification on fluoroscopy and a high calcium score obtained using cardiac computed tomography (see Chapter 18) are not indications for coronary arteriography.

Discussions with patients relating to the risks and benefits of coronary arteriography should be coupled with an outline of the revascularization method in the event that obstructive CAD is identified. Although the performance of CABG generally can be deferred until after a discussion with the cardiac surgeon, the vast majority of PCIs are performed on “ad hoc” basis or at the same time as coronary arteriography.²

Acute Coronary Syndromes

An *early invasive strategy* is defined as diagnostic angiography with an intent to perform revascularization in patients who present with unstable angina or non-ST-segment elevation MI (NSTEMI) (see Table 20-1).⁹ An early invasive strategy is indicated in those patients who have refractory angina or hemodynamic instabilities and in those who initially are stabilized but are at elevated risk for recurrent clinical events⁹ (Table 20-3). An early invasive strategy is reasonable within the first 12 to 24 hours in both patients at high risk and those not at high risk for clinical events.⁹ An early invasive strategy is not recommended in patients with extensive comorbid disease, in whom the risks are likely to outweigh the benefits of revascularization, and in patients with acute chest pain but a low likelihood of an acute coronary syndrome (see Chapters 52 and 53).⁹

Patients who should undergo coronary arteriography are patients with ST-segment elevation MI (STEMI), NSTEMI, or unstable angina who experience spontaneous ischemia; patients who experience ischemia at a minimal workload; and patients in whom MI is complicated by heart failure, hemodynamic instability, cardiac arrest, mitral regurgitation, or ventricular septal rupture.¹⁰ Patients with angina or provokable ischemia after MI also should undergo coronary arteriography, because revascularization may reduce the high risk of reinfarction in such cases.¹⁰

Other Conditions Warranting Coronary Arteriography

Coronary arteriography should be performed in patients scheduled to undergo noncardiac surgery who demonstrate high-risk criteria on noninvasive testing, those with angina unresponsive to medical therapy or unstable angina, and those with equivocal results on noninvasive testing combined with high-risk surgical factors (see Table 20-1).¹¹ Coronary arteriography also is recommended for patients scheduled to undergo surgery for valvular heart disease or congenital heart disease, particularly those with multiple cardiac risk factors and those with infective endocarditis and evidence of coronary embolization (see Chapters 62 to 64).¹¹

TABLE 20-3 Risk Stratification in Patients with Unstable Angina and Non-ST-Segment Elevation Myocardial Infarction

Invasive Strategy Preferred
Recurrent angina or ischemia at rest with low-level activities despite medical therapy
Elevated cardiac biomarkers (TnT or TnI)
New or presumably new ST-segment depression
Signs or symptoms of congestive heart failure or worsening mitral regurgitation
High-risk findings on noninvasive testing
Hemodynamic instability
Sustained ventricular tachycardia
PCI within 6 months
Previous coronary artery bypass graft surgery
High risk score (e.g., TIMI or GRACE)
Mild to moderate renal dysfunction
Diabetes mellitus
Reduced LVEF <40%
Conservative Strategy Preferred
Low risk score (e.g., TIMI, GRACE)
Patient or physician presence in the absence of high-risk features

GRACE = Global Registry of Acute Coronary Events; PCI = percutaneous coronary intervention; TIMI = Thrombolysis in Myocardial Infarction; TnI = troponin I; TnT = troponin T.

Modified from Anderson JL, Adams CD, Antman EM, et al: 2012 ACCF/AHA focused update incorporated into the ACCF/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 61:e179, 2013.

Coronary arteriography should be performed annually in patients after cardiac transplantation (see Chapter 28), even in the absence of clinical symptoms, because of the characteristically diffuse and asymptomatic nature of graft atherosclerosis. Coronary arteriography is useful in potential donors for cardiac transplantation whose age or cardiac risk profile increases the likelihood of CAD.¹¹

Contraindications to Coronary Arteriography. Although there are no absolute contraindications to coronary arteriography, relative contraindications include unexplained fever, untreated infection, severe anemia or active bleeding, critical electrolyte imbalance, uncontrolled systemic hypertension, digitalis toxicity, and ongoing stroke. Other disease states that are relative contraindications to the procedure include acute renal failure, decompensated heart failure, severe intrinsic or iatrogenic coagulopathy (as defined by an elevated international normalized ratio [INR]), and active endocarditis. Risk factors for significant complications after catheterization include advanced age and several general medical, vascular, and cardiac characteristics (Table 20-4).

Inasmuch as most of these conditions are self-limited, deferral of coronary arteriography until important comorbid conditions have been stabilized generally is preferred unless there is evidence of ongoing myocardial necrosis. It is recognized that coronary arteriography performed under emergency conditions is associated with a higher risk for procedural complications. The risks and benefits of the procedure and its alternatives should be carefully reviewed with the patient and family in all circumstances before coronary arteriography is undertaken in the presence of relative contraindications.

COMPLICATIONS OF CORONARY ARTERIOGRAPHY

Major complications are uncommon (<1%) after coronary arteriography^{12,13} (Table 20-5) and include death, MI, and stroke (each occurring with a frequency of approximately 1/1000), contrast agent reactions (less than 1/250) (see Chapter 19) and local vascular complications (less than 1/100).¹⁴ The use of vascular closure devices may reduce vascular complication rates in selected patients.¹⁵ The incidence of death during coronary arteriography is higher in the presence of left main CAD, a LV ejection fraction less than 30%, and New York Heart Association (NYHA) class IV symptoms. Stroke may develop from embolization of atherosclerotic debris into the cerebral circulation or embolization of clot that formed on the injection catheters, particularly in patients with previous CABG who

TABLE 20-4 Patients at Increased Risk for Complications after Coronary Arteriography

Increased General Medical Risk
Age >70 years
Complex congenital heart disease
Morbid obesity
General debility or cachexia
Uncontrolled glucose intolerance
Arterial oxygen desaturation
Severe chronic obstructive lung disease
Renal insufficiency with creatinine concentration >1.5 mg/dL
Increased Cardiac Risk
Three-vessel CAD
Left main CAD
NYHA functional class IV
Significant mitral or aortic valve disease or mechanical prosthesis
Ejection fraction <35%
High-risk findings on exercise treadmill testing (hypotension or severe ischemia)
Pulmonary hypertension
Pulmonary artery wedge pressure >25 mm Hg
Increased Vascular Risk
Anticoagulation or bleeding diathesis
Uncontrolled systemic hypertension
Severe peripheral vascular disease
Recent stroke
Severe aortic insufficiency

Modified from Scanlon P, Faxon D, Audet A, et al: ACC/AHA Guidelines for coronary angiography. *J Am Coll Cardiol* 33:1756, 1999.

TABLE 20-5 Risks Associated with Cardiac Catheterization

COMPLICATION	SCAI REGISTRY RISK (%)
Mortality	0.11
Myocardial infarction	0.05
Cerebrovascular accident	0.07
Arrhythmias	0.38
Vascular complications	0.43
Contrast agent reaction	0.37
Hemodynamic complications	0.26
Perforation of heart chamber	0.03
Other complications	0.28
Total of major complications	1.70

have a diseased ascending aorta. Acute stroke complicating diagnostic catheterization has been amenable to neurovascular intervention, and neurologic changes should be addressed as soon as they are recognized (see Chapter 59).Minor complications also are uncommon (<2%) after coronary arteriography. Air embolus is rare (less than 1 case per 1000 procedures) during diagnostic coronary arteriography and is preventable with meticulous flushing and elimination of air within the manifold (see Chapter 19).¹⁶ If an air embolus and air lock do occur, 100% oxygen should be administered, which allows resorption of smaller amounts of air within 2 to 4 minutes. Larger air emboli have been treated with direct aspiration of air from the coronary artery.¹⁷ Ventricular arrhythmias associated with air embolus can be treated with lidocaine and cardioversion. Reduced anterograde flow, also called no-reflow, occurs in 0.17% of cases, primarily attributable to air embolism, spasm, or dissection.¹⁸⁻²⁰ Cholesterol embolization also is uncommon but may occur with catheter manipulation in a diffusely diseased abdominal or thoracic aorta.²¹ Nerve pain after diagnostic

catheterization is infrequent and generally resolves spontaneously. Although lactic acidosis may develop after coronary angiography in diabetic patients taking metformin, this complication has been minimized with metformin discontinuation before the administration of contrast material and withholding of metformin after coronary arteriography until renal function has recovered.² The presence of chronic kidney disease is also an important predictor of prognosis in patients undergoing coronary angiography (see Chapter 88).²² Universal precautions, including the use of gowns, caps, masks, and protective eyewear, are recommended during cardiac catheterization, with the recognition that carriers of human immunodeficiency virus (HIV) or hepatitis may be asymptomatic.² The risk of infection after coronary arteriography is low.

Radiation Exposure

Radiation exposure may present risk to both the patient and the operator, and two forms of radiation injury have been described: deterministic injury and stochastic injury.^{2,23} Deterministic injury occurs when the radiation dose is sufficient to result in cell death and creates organ dysfunction.^{2,23} Deterministic injury is dose-dependent, most commonly resulting in skin injury. Stochastic injury results in genetic mutations, and is not dose-dependent.^{2,23} Radiation dose is measured as either of two entities: the total radiation exposure, determined from the output of the x-ray tube and expressed as the *dose-area product* (DAP), and the *interventional reference point (IRP) dose*, which is an estimation of the radiation dose to the patient's skin.^{2,23} With the expanded use of complex PCI, patients may now return for multiple procedures during their lifetime that may subject them to the risk of cumulative radiation injury. For example, an average PCI procedure imparts 150 times the radiation exposure received with a single chest radiograph and 6 times the annual radiation received as background environmental radiation. Radiation dosage may vary by up to 10-fold in patients undergoing coronary arteriography and interventional procedures. Radiation exposure can be minimized by reducing the acquisition frame rate, decreasing fluoroscopic imaging time, use of pulse fluoroscopy, avoiding high magnification, using image collimators and filters, lowering the image detector as low as possible, and avoiding highly angulated views.^{2,23,24} Reports of radiodermatitis related to prolonged x-ray exposure have led to the recommendation that patients who undergo fluoroscopy for longer than 60 minutes or receive more than 7500 mGy be counseled regarding the delayed effects of radiation injury to the skin. Proportionately more radiation is received with digital angiography than with fluoroscopy alone.²⁵ Radiation-induced lesions generally are identified by their location in the region of the x-ray tube and are manifested as an acute erythema, delayed pigmented telangiectasia, and indurated or ulcerated plaques in the upper back or below the axilla.²

TECHNIQUE OF CORONARY ARTERIOGRAPHY

Preparation of the Patient

Elective coronary arteriography should be performed alone or in conjunction with right-heart catheterization or contrast-enhanced left ventriculography when comorbid conditions such as heart failure, diabetes mellitus, or renal insufficiency are stable. Routine laboratory examinations should include hemoglobin determination, platelet count, electrolyte panel, and serum creatinine assay performed less than 2 weeks before the procedure.² If patients are not taking warfarin and do not have liver disease or a known coagulopathy, a prothrombin time is no longer required.² Coronary arteriography can be safely performed in patients on aspirin, unfractionated heparin, low molecular weight heparin, and glycoprotein IIb/IIIa inhibitors without interruption.² Warfarin should be discontinued 3 days before elective coronary arteriography, and the INR should be 1.8 or less for femoral cases and 2.2 or less before radial cases, although radial catheterization has been performed safely with higher INR values (up to 2.5).^{2,26} Dabigatran should be stopped 24 hours before the procedure if the glomerular filtration rate (GFR) is higher than 50 mL/min and 48 hours before the procedure if the GFR is between 30 and 50 mL/min.² Metformin should be withheld in diabetic patients before the procedure and should not be restarted after the procedure until the renal function has normalized.²

Patients at increased risk for systemic thromboembolism on withdrawal of warfarin, such as those with atrial fibrillation, mitral valve disease, or previous history of systemic thromboembolism, may be treated with intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin in the periprocedural period. A “time-out” check should be performed at the beginning of the procedure to verify the name of the patient, the procedure to be performed, the signed consent, allergies, antibiotic administration, and other pertinent clinical information that will enhance patient safety.²

Vascular Access

A variety of vascular approaches are available for coronary arteriography. The selection of the vascular access depends on operator and patient preferences, anticoagulation status, and presence of peripheral vascular disease.

Femoral Artery Approach

The right and left femoral arteries are the most commonly used access sites for coronary arteriography (see Chapter 19). The common femoral artery courses medially to the femoral head, and the bifurcation of the common femoral artery into its branches generally is distal to the middle third of the femoral head, which can be localized by means of fluoroscopy before arterial cannulation. The anterior wall of the common femoral artery should be punctured several centimeters below the inguinal ligament but proximal to the bifurcation of the superficial femoral and profunda arterial branches (see Fig. 19-4). If the puncture site is proximal to the inguinal ligament, hemostasis after the procedure may be difficult to achieve with manual compression, leading to an increased risk of retroperitoneal hemorrhage. If the puncture site is at or distal to the femoral bifurcation, the procedure carries a higher risk of pseudoaneurysm formation after sheath removal. Ipsilateral cannulation of the femoral artery and femoral vein also is associated with increased risk of arteriovenous fistula formation. Optimal femoral artery cannulation can be facilitated with vascular ultrasound guidance.

Femoral artery sheaths can be removed when the activated clotting time is less than 180 seconds. Patients should be confined to bed rest for 1 to 2 hours after the removal of a 4F or 5F sheath and for 2 to 4 hours after the removal of a 6F to 8F sheath, or longer if there is higher risk of bleeding.² Vascular closure devices also may be used, provided that a femoral angiogram confirms presence of the sheath in the common femoral artery.²

Brachial Artery Approach

Although Sones first introduced the cutdown approach to the brachial artery for coronary arteriography, percutaneous access to the brachial and radial arteries is now most often used.²⁷ These approaches are preferred to the femoral approach in the presence of severe peripheral vascular disease and morbid obesity. The brachial artery easily accommodates an 8F (1F = 0.33-mm diameter) sheath.²⁷ A specific risk associated with the brachial artery approach is compromise of the blood supply to the forearm and hand in the event of a vascular complication.

Radial Artery Approach

Radial artery access generally is preferred to brachial access because of its ease of catheter entry and removal and the dual blood supply with the ulnar artery to the hand.^{28,29} The radial artery is an increasingly utilized access site for coronary arteriography, now used in up to 20% of diagnostic procedures in the United States. An Allen test is performed before the procedure to determine the adequacy of ulnar arterial flow, using plethysmography or assessment of palmar hand color during manual compression of the radial artery. Systemic anticoagulation with unfractionated heparin (up to 5000 units) or bivalirudin is used for both brachial and radial artery approaches.³⁰ Use of a hydrophilic sheath and intra-arterial administration of verapamil and nitroglycerin will reduce the occurrence of radial artery spasm, although rare episodes of radial artery trauma and avulsion have been reported. The long-term radial artery patency rate also may be

improved with use of a compression device that allows perfusion of the hand during hemostasis.³¹ Several anatomic factors are associated with an unsuccessful transradial access, including a high-bifurcation radial origin, full radial loop, and extreme radial artery tortuosity.³²

The radial artery approach allows immediate ambulation after coronary arteriography with lower cost (compared with femoral closure devices), improved coronary visualization (compared with smaller-diameter [4F] femoral catheters), and reduced bleeding complications (compared with femoral access).³³ Saphenous vein grafts (SVGs) can be engaged with use of either radial artery, but cannulation of the internal mammary artery (IMA) is best performed from the left radial artery. Engagement of the left IMA from the right radial artery is technically challenging but may be accomplished by means of a “headhunter” or another shaped catheter for selective entry into the left subclavian artery. A 0.035-inch angled hydrophilic guidewire is the most useful support wire for access to the subclavian artery. The radial artery generally will accommodate 4F to 6F catheters.

Catheters

Diagnostic catheters developed for coronary arteriography generally are constructed from polyethylene or polyurethane with a fine wire braid within the wall to allow advancement and directional control (torque) and to prevent kinking. The outer diameter size of the catheters ranges from 4F to 8F, but 5F and 6F catheters are used most commonly for diagnostic arteriography.

Judkins Catheters. The Judkins left catheter is preshaped to allow entry into the left coronary ostium from the femoral approach with minimal catheter manipulation (Figs. 20-1 and 20-2). A pre-formed Judkins left catheter can also be used from the left or right brachial or radial artery, but a catheter with 0.5 cm less curvature than required for the femoral approach generally is better suited for coronary cannulation. The Judkins right catheter is shaped to permit entry into the right coronary artery (RCA) with a small amount of rotational (clockwise) catheter manipulation from any vascular approach.

Selection of Judkins catheter shape is based on the body habitus of the patient and the size of the aortic root. The left coronary artery (LCA) is easily engaged with the Judkins left 4.0 catheter from the femoral approach in most patients, whereas patients with a dilated ascending aorta (e.g., in the setting of congenital aortic stenosis and aortic root dilation) may require the use of a Judkins left 5.0 or 6.0 catheter. In patients with large ascending aortic aneurysms, heat modification of catheters to achieve Judkins left 7.0 to 10.0 shapes may be required for successful arteriography. Use of a Judkins shape

FIGURE 20-1 Right (R) and left (L) Judkins catheters. The primary (upper arrow) and secondary (lower arrow) curves of the Judkins left catheter are shown.

that is too small for the ascending aorta often leads to folding of the catheter within the aortic root. The best technique for removal of a folded Judkins left catheter from the body involves withdrawing the folded catheter into the descending aorta and advancing a guidewire antegrade in the contralateral common iliac artery. On withdrawal of the catheter and guidewire together, the catheter straightens and can be removed safely from the body without disruption of the arterial access site.

Amplatz Catheters. Amplatz catheters can be used for the femoral or brachial approach to coronary arteriography (Fig. 20-3). The Amplatz catheters constitute an excellent alternative in cases in which the Judkins catheter is not appropriately shaped to enter the

coronary arteries. The Amplatz L-1 or L-2 catheter may be used for coronary angiography from the right brachial or radial approach. A modified Amplatz right catheter (AR-1 or AR-2) can be used for engagement of a horizontal or upward takeoff RCA or SVG.

Other Catheters. Other catheters used for coronary arteriography include the IMA left catheter with an angulated tip that allows engagement of the IMA or an upward takeoff RCA. Catheter shapes that permit engagement of SVGs include the multipurpose catheter (Fig. 20-4) and the Judkins right, modified Amplatz right, and hockey stick catheters. Specially designed catheters for engagement of the coronary arteries from the radial artery also have been developed.

Drugs Used During Coronary Arteriography Analgesics

The goal of analgesic use is to achieve a state of conscious sedation, defined by a minimally depressed level of consciousness that allows the patient to respond appropriately to verbal commands and to maintain a patent airway.^{34,35} Several different sedation regimens are recommended, but depending on the patient's comorbid conditions, most operators use diazepam, 2.5 to 10 mg orally, and diphenhydramine, 25 to 50 mg orally, 1 hour before the procedure. Intravenous midazolam, 0.5 to 2 mg, and fentanyl, 25 to 50 µg, are useful agents to provide sedation during the procedure. Patients undergoing conscious sedation should have continuous hemodynamic, electrocardiographic, and oximetry monitoring as well as access to oxygen and suction ports and a resuscitation cart.

Anticoagulants

Intravenous unfractionated heparin is no longer required during routine coronary arteriography. Patients at increased risk for thromboembolic complications, including those with severe aortic stenosis, critical peripheral arterial disease, or arterial atheroembolic disease, and those undergoing procedures necessitating prolonged (>1 to 2 minutes) use of guidewires in the central circulation may be given intravenous unfractionated heparin, 2000 to 5000 units. Patients undergoing brachial or radial artery catheterization should also receive systemic anticoagulation with unfractionated heparin or bivalirudin. Frequent flushing of all diagnostic and guiding catheters with heparinized saline will prevent the formation of microthrombi within the catheter tip. A continuous flush through the arterial access sheath may also lower the occurrence of distal thromboembolism.

The anticoagulant effect of unfractionated heparin can be reversed with protamine, 1 mg for every 100 units of heparin. Protamine causes anaphylaxis or serious hypotensive episodes in approximately 2% of patients and should not be administered to patients with previous exposure to NPH insulin, those with a history of unstable angina or high-risk coronary anatomy, or those who have undergone coronary arteriography using the brachial or radial artery.

Treatment of Periprocedural Ischemia

Patients may experience angina during coronary arteriography because of ischemia induced by tachycardia, hypertension, contrast agents, microembolization, coronary spasm or enhanced vasomotor tone, or dynamic platelet aggregation. Sublingual (0.3 mg), intracoronary (50 to 200 µg), or intravenous (10 to 25 µg/min) nitroglycerin can be given to patients with a systolic blood pressure above 100 mm Hg. Patients without contraindications to beta blockers, such as bradycardia, bronchospasm, or LV dysfunction, can be given intravenous metoprolol, 2.5 to 5.0 mg, or propranolol, 1 to 4 mg. Intra-aortic balloon counterpulsation also is a useful adjunct in patients with coronary ischemia and left main CAD, cardiogenic shock, or refractory pulmonary edema.

Contrast Agents

All radiographic contrast agents contain iodine, which effectively absorbs x-rays in the energy range of the angiographic imaging system. Radiographic contrast agents currently used for coronary arteriography also may produce a number of adverse hemodynamic, electrophysiologic, and renal effects (see Chapter 19). The frequency of these side effects varies among the available radiocontrast agents because of differences in their ionic content, osmolality, and viscosity.

Contrast Properties Including Side Effects

The monomeric ionic contrast agents initially used for coronary arteriography were the high-osmolality meglumine and sodium salts of diatrizoic acid. These substances dissociate into cations and iodine-containing anions with a higher serum osmolality (>1500 mOsm) than that of human plasma (300 mOsm). As a result of their hypertonicity, these compounds produced sinus bradycardia, heart block, QT interval and QRS prolongation, ST-segment depression, giant T

wave inversion, decreased LV contractility, decreased systolic pressure, and increased LV end-diastolic pressure, with the calcium-chelating properties of these agents also contributing to their cardiac effects. Ventricular tachycardia and fibrillation occurred in 0.5% of cases and developed more often when ionic contrast agents were injected into a damped (ventricularized) coronary catheter, were given too rapidly, or were administered in too great a volume. Because of the availability of other, less toxic contrast agents, ionic contrast agents are now rarely used for coronary arteriography. Nonionic agents (see Chapter 19) do not ionize in solution and provide more iodine-containing particles per milliliter of contrast material than do ionic agents. Their osmolality is substantially reduced (<850 mOsm) because these agents exist in solution as single neutral molecules and do not chelate calcium, potentially leading to fewer side effects.

As noted, side effects also may occur after use of nonionic radiocontrast agents, related in part to the hyperosmolality of these agents. Such unwanted reactions include hot flushing, nausea, vomiting, and arrhythmias. Hypotension after contrast medium administration may be due to an anaphylactoid reaction, a direct toxic effect, or a vasovagal reaction. No selective advantage on the prevention of contrast-induced nephropathy has been shown with any of the class of nonionic agents.

Contrast-Induced Nephropathy

Worsening of renal function may occur after contrast administration in 10% to 20% of patients, especially in those with previous renal insufficiency, diabetes mellitus, dehydration before the procedure, heart failure, larger volumes of contrast material, and recent (within 48 hours) exposure to contrast material.³⁶ The patients at highest risk for this complication are those with diabetes mellitus and an estimated glomerular filtration rate below 60 mL/min.² Fluid administration with intravenous saline or sodium bicarbonate at 1.0 mL/kg/min to 1.5 mL/kg/min for 3 to 12 hours before the procedure and 6 to 12 hours after the procedure is recommended to reduce the risk of contrast nephropathy.^{2,37-39} Acetylcysteine is no longer recommended for contrast nephropathy prevention.² Low-osmolality or iso-osmolar contrast media should be used judiciously, with a contrast volume-to-creatinine clearance ratio greater than 3.7 as a ceiling for contrast load.²

Contrast Reaction Prophylaxis

Reactions to radiocontrast agents are classified as mild—grade I: single episode of emesis, nausea, sneezing, or vertigo; moderate—grade II: hives or multiple episodes of emesis/fevers/chills; or severe—grade III: clinical shock, bronchospasm, laryngospasm or laryngeal edema, loss of consciousness, hypotension, hypertension, cardiac arrhythmias, angioedema, or pulmonary edema. Although mild or moderate reactions occur in approximately 9% of patients, severe reactions are uncommon (0.2% to 1.6%).⁴⁰ Reactions to contrast agents may be more difficult to manage in patients receiving beta blocker therapy. Recurrence rates may approach 50% on repeat exposure to contrast agents, and prophylactic use of H₁ and H₂ histamine receptor-blocking agents and aspirin therapy has been recommended.² In a meta-analysis of nine trials addressing the value of premedication in patients with a history of reactions to contrast agents, a 70% reduction in the occurrence of grade III reactions was associated with pretreatment with corticosteroids (from 0.9% to 0.2% in premedicated patients).⁴⁰ Despite the high number needed to treat (NNT) to prevent a contrast allergy, pretreatment is still recommended, and patients with a suspected severe previous reaction to a contrast agent should receive two doses of prednisone, 60 mg (or its equivalent), the night before and again at 2 hours before the procedure. Diphenhydramine, 50 mg, and cimetidine, 300 mg, also may be given before the procedure. A shellfish allergy is no longer considered a risk factor for contrast reactions.²

Anatomy and Variations of the Coronary Arteries

The historic principle of radiographic coronary imaging is that radiation produced by the x-ray tube is attenuated as it passes through the

body and is detected by the image intensifier. Iodinated contrast medium injected into the coronary arteries enhances the absorption of x-rays and produces a sharp contrast with the surrounding cardiac tissues. The x-ray shadow is then converted into a visible light image by an image intensifier, displayed on fluoroscopic monitors, and stored on a digital storage system. Digital imaging is preferred to the use of 35-mm cinefilm for coronary angiography because of its versatility with respect to image transfer, low-cost acquisition and storage, and capability for image enhancement after image acquisition, albeit at slight lower resolution. Flat-panel detectors have replaced image intensifiers and have eliminated the analog-to-digital converters of the conventional image intensifiers. This advance has resulted in reduced radiation exposure and enhanced image quality.

The major epicardial branches and their second- and third-order branches can be visualized by coronary arteriography. The network of smaller intramyocardial branches generally is not seen because of their size, cardiac motion, and limitations in resolution of angiographic systems. These fourth-order-and-beyond “resistance” vessels play a major role in autoregulation of coronary blood flow, may limit myocardial perfusion during stress, and contribute to ischemia in patients with LV hypertrophy or systemic hypertension (see Chapter 49). Coronary perfusion in these smaller branch vessels can be quantitatively assessed by use of the myocardial blush score, which has important prognostic significance in patients with STEMI and those undergoing PCI.⁴¹

Arterial Nomenclature and Extent of Disease. The Coronary Artery Surgery Study (CASS) investigators established the nomenclature most commonly used to describe the coronary anatomy, defining 27 segments in three major coronary arteries (Table 20-6). The Bypass Angioplasty Revascularization Investigators (BARI) modified these criteria by addition of two segments for the ramus intermedius and the third diagonal branch. In this system, the three major coronary arteries include the left anterior descending (LAD) artery, left circumflex (LCx) artery, and RCA with a right-dominant, balanced, or left-dominant circulation, defined by the presence of the posterior descending and adjacent posterolateral branch. CAD is defined as a 50% or greater diameter stenosis in one or more of these vessels, although it is clear that stenoses of less than 50% have major prognostic implications because these lesions most commonly lead to plaque rupture and acute coronary syndromes. Subcritical stenoses of less than 50% are best characterized as nonobstructive CAD; obstructive CAD is classified as one-, two-, or three-vessel disease.⁴²

A number of “jeopardy scores” were developed to quantitate plaque burden, to predict patient-based clinical outcomes, and to identify risk factors for the presence of atherosclerosis and its progression. The Califf scoring system divided the coronary circulation into

six segments with two points allotted for each coronary stenosis of 75% or more (score range, 0 to 12). The Gensini scoring system used an ordinal ranking based on stenosis severity in 11 coronary segments (score range, 0 to 72). The Candell-Riera scoring system used an ordinal ranking (from 1 to 5) of 13 coronary segments (score range, 0 to 65). In CASS, the major determinants of 6-year outcome were the number of diseased vessels, the number of diseased proximal segments, and the global LV function; these three factors accounted for 80% of the prognostic information; the differences among the various scoring systems related to their definitions, rather than to their ability to provide unique information. More recently, the SYNTAX Score has been developed to assess early and late outcomes after PCI and CABG in patients with multivessel CAD (see later under [Assessing Lesion Complexity](#)).

Angiographic Projections. The major coronary arteries traverse the interventricular and atrioventricular grooves, aligned with the long and short axes of the heart, respectively. Because the heart is oriented obliquely in the thoracic cavity, the coronary circulation generally is visualized in the right anterior oblique (RAO) and left anterior oblique (LAO) projections to furnish true posteroanterior and lateral views of the heart, but these views are limited by vessel foreshortening and superimposition of branches. Simultaneous rotation of the x-ray beam in the sagittal plane provides a better view of the major coronary arteries and their branches. A simple nomenclature has evolved for the description of these sagittal views that characterizes the relationship between the image intensifier and the patient. Assuming that the x-ray source is under the patient’s table and the image detector is over the patient’s table, the projection is referred to as the cranial view if the image detector is tilted toward the head of the patient. The projection is referred to as the caudal view if the image detector is tilted down toward the feet of the patient.

It is difficult to predict which angulated views will be most useful for any particular patient because the “optimal” angiographic projection depends largely on body habitus, variation in the coronary anatomy, and location of the lesion. It is recommended that the coronary arteries be visualized in both the LAO and RAO projections with both cranial and caudal angulation. Obtaining at least two views of the left (Fig. 20-5) and right (Fig. 20-6) coronary arteries is recommended.

Left Coronary Artery

The Judkins left 4.0 coronary catheter is used most often to engage the LCA (Fig. 20-7). If the Judkins left catheter begins to turn out of profile (so that one or both curves of the catheter are no longer visualized en face), it can be rotated clockwise very slightly and advanced slowly to enter the left sinus of Valsalva, permitting the catheter tip to engage the ostium of the LCA. When the ascending aorta is dilated or the aortic arch is unfolded, advancement of the Judkins left 4.0

TABLE 20-6 Classification System for Coronary Segments

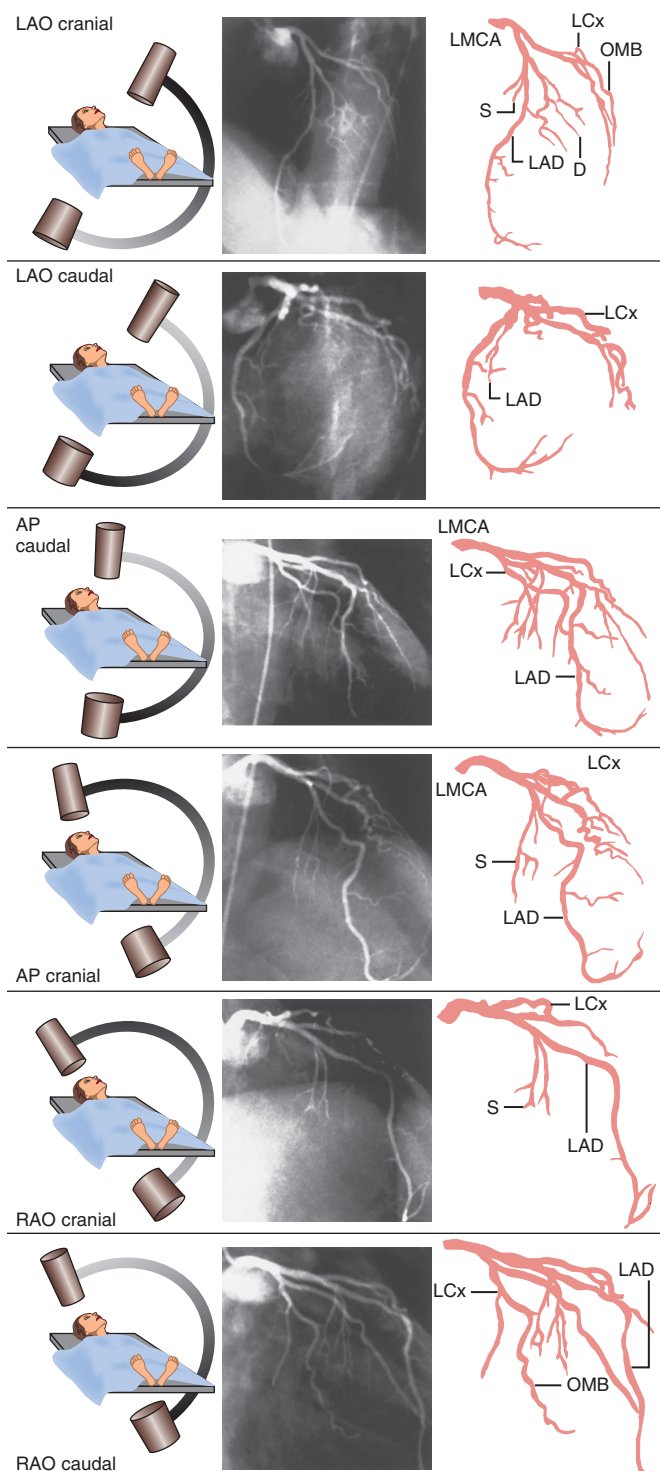

FIGURE 20-5 Angiographic views of the LCA. The approximate positions of the x-ray tube and image intensifier are shown for each of the commonly used angiographic views. **LAO cranial**, The 60-degree LAO view with 20 degrees of cranial angulation shows the ostium and distal portion of the LMCA, the middle and distal portions of the LAD artery, septal perforators, diagonal branches, and the proximal LCx artery and superior OMB. **LAO caudal**, The 60-degree LAO view with 25 degrees of caudal angulation shows the proximal LMCA and the proximal segments of the LAD and LCx arteries. **AP caudal**, The AP projection with 20 degrees of caudal angulation shows the distal LMCA and proximal segments of the LAD and LCx arteries. **AP cranial**, The AP projection with 20 degrees of cranial angulation also shows the midportion of the LAD artery and its septal branches. **RAO cranial**, The 30-degree RAO projection with 20 degrees of cranial angulation shows the course of the LAD artery and its septal and diagonal branches. **RAO caudal**, The 30-degree RAO projection with 25 degrees of caudal angulation shows the LCx and OMBs. D = diagonal branch(es); OMB = obtuse marginal branch; S = septal perforator(s).

FIGURE 20-6 Angiographic views of the RCA. The approximate positions of the x-ray tube and the image intensifier are shown for each of the commonly used angiographic views. **LAO straight**, The 60-degree LAO view shows the proximal and middle portions of the RCA as well as the acute marginal branches (AMB) and termination of the RCA in the posterior left ventricular branches (PLV). **LAO cranial**, The 60-degree LAO view with 25 degrees of cranial angulation shows the midportion of the RCA and the origin and course of the PDA. **RAO straight**, The 30-degree RAO view shows the midportion of the RCA, the conus branch, and the course of the PDA.

coronary catheter may result in the formation of an acute secondary angle of the catheter, pointing the tip of the catheter upward, away from the left coronary ostium. Further advancement of the Judkins left catheter in this position should be avoided because the catheter will then prolapse on itself and become folded in the ascending aortic arch. In the event of this mishap, a guidewire can be temporarily reinserted into the catheter to straighten the secondary bend, permitting the catheter to be advanced to the left sinus of Valsalva. If the ascending aorta is significantly dilated, a large Judkins left 5.0 or 6.0 should be used. If the tip of the Judkins left catheter advances beyond the ostium of the LCA without engagement, the primary bend of the catheter can be reshaped by further careful advancement and prompt withdrawal of the catheter, allowing the tip to "pop" into the ostium of the LCA. This maneuver, along with gentle clockwise or counterclockwise rotation, frequently permits selective engagement of the LCA when the initial attempt has failed. If the catheter tip is located below the origin of the LCA, as in the case of a smaller aortic root, a shorter Judkins left 3.5 catheter can be used to allow coaxial engagement of the LCA.

Use of the Amplatz left catheters to cannulate the LCA requires more catheter manipulation than with the standard Judkins left catheter. In this circumstance, the broad secondary curve of the Amplatz left 1 or 2 catheter is positioned so that it rests on the right aortic cusp with its tip pointing toward the left aortic cusp. Alternating advancement and retraction of the catheter with slight clockwise rotation allows the catheter tip to advance slowly and superiorly along the left sinus of Valsalva to enter the LCA ostium. When the tip enters the ostium, the position of the catheter usually can be stabilized with slight retraction of the catheter. After the LCA ostium has been

FIGURE 20-7 **A**, Push-pull technique for catheterization of the LCA with the Judkins left catheter. In the LAO view, the coronary catheter is positioned in the ascending aorta over a guidewire, and the guidewire is removed. The catheter is advanced so that the tip enters the left sinus of Valsalva. **B**, If the catheter does not selectively engage the ostium of the LCA, further slow advancement into the left sinus of Valsalva creates a temporary acute angle at the catheter. Prompt withdrawal of the catheter allows easy entry into the artery.

cannulated, the pressure at the tip of the catheter should be checked immediately to ensure that there is no damping or ventricularization of the pressure contour. If a damped or ventricularized pressure tracing is obtained, the catheter should immediately be removed from the LCA, and an attempt at repositioning should be made. If abnormal pressure recording persists, the catheter should be withdrawn from the LCA, and a nonselective injection of contrast medium into the LCA should be performed, using the anteroposterior (AP) projection to evaluate the LMCA. If the pressure measured at the catheter tip is normal and a test injection of contrast agent suggests the absence of LMCA disease, left coronary arteriography is then performed using standard techniques. To remove the Amplatz left catheter from the LCA, the catheter should be advanced forward in the vessel to disengage its tip superiorly from the coronary ostium. Simply withdrawing the Amplatz left catheter results in deep seating of the catheter tip within the LCA, potentially resulting in catheter-induced arterial dissection.

Left Main Coronary Artery

The LMCA arises from the superior portion of the left aortic sinus, just below the sinotubular ridge of the aorta, which defines the border separating the left sinus of Valsalva from the smooth (tubular) portion of the aorta. The LMCA ranges in diameter from 3 to 6 mm and may be up to 10 to 15 mm in length. The LMCA courses behind the right ventricular outflow tract and usually bifurcates into the LAD artery and LCx branches. Rarely, the LMCA is absent, and the LAD and LCx arteries have separate ostia. The LMCA is best visualized in the AP projection with slight (0 to 20 degrees) caudal angulation, but it should be viewed in several projections with the vessel off the spine to exclude LMCA stenosis (Figs. 20-8 and 20-9).

Left Anterior Descending Artery

The LAD artery courses along the epicardial surface of the anterior interventricular groove toward the cardiac apex. In the RAO projection, it extends along the anterior aspect of the heart; in the LAO projection, it passes down the cardiac midline, between the right and left ventricles (see Fig. 20-5).

The major branches of the LAD artery are the septal and diagonal branches. The septal branches arise from this vessel at approximately 90-degree angles and pass into the interventricular septum, varying in size, number, and distribution. In some cases, a large first septal branch that is vertically oriented divides into a number of secondary “pitchforking” branches that ramify throughout the septum. In other cases, a more horizontally oriented, large first septal branch is present that passes parallel to the LAD itself within the myocardium. In still other cases, a number of septal arteries roughly comparable in size are present. These septal branches interconnect with similar septal branches passing upward from the posterior descending branch of the RCA to produce a network of potential collateral channels. The interventricular septum is the most densely vascularized area of the heart.

The diagonal branches of the LAD artery pass over the anterolateral aspect of the heart. Although virtually all patients have a single LAD in the anterior interventricular groove, wide variability in the number and size of diagonal branches has been documented. Most patients (90%) have one to three diagonal branches, and acquired atherosclerotic occlusion of the diagonal branches should be suspected if no diagonal branches are seen, particularly with unexplained contraction abnormalities of the anterolateral left ventricle. Visualization of the origin of the diagonal branches often requires very steep (50 to 60 degrees) LAO and angulated cranial (20 to 40 degrees) skews.

In some patients, the LMCA trifurcates into the LAD and LCx arteries and the ramus intermedius. When it is present, the ramus intermedius arises between the LAD and the LCx arteries. This vessel is analogous to either a diagonal branch or an obtuse marginal branch, depending on its anterior or posterior course along the lateral aspect of the left ventricle. In most patients (80%), the LAD courses around the LV apex and terminates along the diaphragmatic aspect of the left ventricle. In the remaining patients, the LAD fails to reach the diaphragmatic surface, terminating instead either at or before the cardiac apex. In this circumstance, the posterior descending branch (posterior descending artery [PDA]) of the RCA or LCx artery is larger and longer than usual and supplies the apical portion of the ventricle.

The best angiographic projections for viewing the course of the LAD artery are the cranially angulated LAO, AP, and RAO views. The LAO cranial view displays the midportion of the LAD and separates the diagonal and septal branches. The RAO cranial view displays the proximal, middle, and distal segments of the LAD and allows separation of the diagonal branches superiorly and the septal branches inferiorly. The AP view, requiring cranial (20 to 40 degrees) skew, often projects the midportion of the LAD, separating the vessel from its diagonal and septal branches. The LAO caudal view also displays the origin of the LAD in a horizontally oriented heart, and the AP caudal or shallow RAO caudal view visualizes the proximal LAD as it arises from the LMCA. The RAO caudal projection also is useful for visualization of the distal LAD and its apical termination.

In some patients with no LMCA but separate ostia for the LAD and LCx arteries, the LAD generally has a more anterior origin than the LCx. The LAD can be engaged with the Judkins left catheter in this setting with paradoxical counterclockwise rotation, which rotates the secondary bend of the catheter to a posterior position in the aorta and turns the primary bend and tip of the catheter to an anterior position. The opposite maneuver may be used to engage the LCx selectively in the setting of separate LAD and LCx ostia. A Judkins catheter with a larger curve, such as a Judkins left 5.0, selectively engages the downward-coursing LCx, and a catheter with a shorter curve, such as a Judkins left 3.5, tends to engage selectively the more anterior and superior LAD.

FIGURE 20-8 Intermediate LMCA stenosis evaluated with IVUS. **A**, Left coronary arteriography in the standard RAO projection with caudal angulation (arrow indicates distal LMCA). **B**, The LAO projection with caudal angulation shows a tapered stenosis of the LMCA (arrow). **C**, IVUS image of the proximal LMCA shows a minimal cross-sectional area of 16 mm² (white outline). **D**, IVUS image of the distal LMCA shows stenosis with a luminal cross-sectional area of 6.5 mm² (white outline), which is consistent with a hemodynamically significant LMCA stenosis.

FIGURE 20-9 Severe stenosis of the distal LMCA. **A**, RAO projection with caudal angulation demonstrates a severe ulcerated stenosis in the distal portion of the LMCA (arrow). **B**, An AP view with cranial angulation demonstrates this stenosis in a second view. Limited coronary arteriography should be performed when severe LMCA stenosis (arrow) has been demonstrated.

Left Circumflex Artery

The LCx artery originates from the LMCA and courses within the posterior (left) atrioventricular groove toward the inferior interventricular groove (see Fig. 20-5). The LCx artery is the dominant vessel in 15% of patients, supplying the left PDA from the distal continuation of the LCx. In the remaining patients, the distal LCx varies in size and length, depending on the number of posterolateral branches supplied by the distal RCA. The LCx usually gives off one to three large obtuse marginal branches as it passes down the atrioventricular groove. These are the principal branches of the LCx, because they supply the lateral free wall of the left ventricle. Beyond the origins of the obtuse marginal branches, the distal LCx tends to be small. The actual position of the LCx can be determined in the late phase of a left coronary injection when the coronary sinus becomes opacified with diluted contrast material.

The RAO caudal and LAO caudal projections are best for visualization of the proximal and middle segments of the LCx and obtuse marginal branches. AP (or 5- to 15-degree RAO) caudal projections also show the origins of the obtuse marginal branches. More severe rightward angulation often superimposes the origins of the obtuse marginal branches on the LCx. If the LCA is dominant, the optimal projection for the left PDA is the LAO cranial view. The LCx artery also gives rise to one or two left atrial circumflex branches. These branches supply the lateral and posterior aspects of the left atrium.

Right Coronary Artery

Cannulation of the origin of the RCA is also performed in the LAO position but requires maneuvers different from those for cannulation of the LCA. Whereas the Judkins left catheter naturally seeks the ostium of the LCA, the Judkins right or modified Amplatz catheters must be rotated to engage the vessel. This entry maneuver usually is accomplished by first passing the catheter to a point just superior to the aortic valve in the left sinus of Valsalva, with the tip of the catheter facing rightward, and then rotating the catheter clockwise while it is withdrawn slightly, which forces the tip to move anteriorly from the left sinus of Valsalva to the right sinus of Valsalva below the sinotubular ridge (Fig. 20-10). Sudden rightward and downward movement of the catheter tip signifies the entry into the RCA ostium. If the ostium of

FIGURE 20-10 Cannulation of the RCA with the Judkins right catheter. **A**, The catheter is advanced to a point just superior to the aortic valve in the left sinus of Valsalva with the tip of the catheter facing rightward, and then the catheter is rotated clockwise while being withdrawn slightly. **B**, Sudden rightward and downward movement of the catheter tip signifies its entry into the RCA ostium.

the RCA is not easily located, the most common reason is that the ostium has a more superior and anterior origin than anticipated. Repeated attempts to engage the RCA should be made at a level slightly more distal to the aortic valve. Nonselective contrast agent injections in the right sinus of Valsalva may reveal the site of the origin of the RCA. Positioning of an Amplatz left catheter in the ostium of the RCA requires a technique similar to that used with the Judkins right catheter. If a gentle attempt to withdraw the Amplatz catheter results in paradoxical deep entry into the RCA, removal of the catheter can be achieved by clockwise or counterclockwise rotation and advancement to prolapse the catheter into the aortic sinus.

An abnormal pressure tracing showing damping or ventricularization may suggest the presence of an ostial stenosis or spasm, selective engagement of the conus branch, or deep intubation of the RCA. If an abnormal pressure tracing has been encountered, the catheter tip should be gently rotated counterclockwise and the catheter withdrawn slightly in an effort to free its tip. With persistent damping, a very small amount of contrast medium (<1 mL) can be injected carefully and the catheter immediately withdrawn in a “shoot-and-run” maneuver, which may allow the cause of damping to be identified. The frequency of ventricular fibrillation and iatrogenic coronary dissection is higher when the RCA is injected in the presence of a damped pressure tracing. If the pressure tracing is normal on entry into the RCA, the vessel should be imaged in at least two projections. The initial injection should be gentle because of the possibility that forceful injection through a catheter whose tip is immediately adjacent to the vessel wall also may lead to dissection. Coronary spasm of the RCA ostium also may occur as a result of catheter intubation. When an ostial stenosis of the RCA is seen, intracoronary nitroglycerin or calcium channel antagonists may be useful in excluding catheter-induced spasm as a cause of the coronary artery narrowing.

The RCA originates from the right anterior aortic sinus somewhat inferior to the origin of the LCA (see Fig. 20-6). It passes along the

right atrioventricular groove toward the crux (a point on the diaphragmatic surface of the heart where the anterior atrioventricular groove, the posterior atrioventricular groove, and the inferior interventricular groove coalesce). The first branch of the RCA is generally the conus artery, which arises at the RCA ostium or within the first few millimeters of the RCA in approximately 50% of patients. In the remaining patients, the conus artery arises from a separate ostium in the right aortic sinus just above the RCA ostium. The second branch of the RCA is usually the sinoatrial node artery. It has been found that this vessel arises from the RCA in just under 60% of patients, from the LCx artery in just under 40%, and from both arteries with a dual blood supply in the remaining cases. The midportion of the RCA usually gives rise to one or several medium-sized acute marginal branches. These branches supply the anterior wall of the right ventricle and may provide collateral circulation in patients with LAD occlusion. The RCA terminates in a PDA and one or more right posterolateral branches.

Because the RCA traverses both the atrioventricular and the interventricular grooves, multiple angiographic projections are needed to visualize each segment of the RCA. The ostium of the RCA is best evaluated in the LAO views, with or without cranial or caudal angulation. The left lateral view also is useful for visualization of the ostium of the RCA in difficult cases. The ostium is identified by the reflux of contrast material from the RCA, which also delineates the aortic root with swirling of contrast in the region of the ostium. The proximal RCA generally is evaluated in the LAO cranial or LAO caudal projection but is markedly foreshortened in the RAO projections. The midportion of the RCA is best seen in the LAO cranial, RAO, and left lateral projections. The origin of the PDA and the posterolateral branches are best evaluated in the LAO cranial or AP cranial view, whereas the midportion of the PDA can be shown in the AP cranial or RAO projection.

Right Coronary Artery Dominance

The RCA is dominant in 85% of patients (Figs. 20-11 to 20-13), supplying the PDA and at least one posterolateral branch (right dominant). The PDA courses in the inferior interventricular groove and gives rise to a number of small inferior septal branches, which pass upward to supply the lower portion of the interventricular septum and interdigitate with superior septal branches passing down from the LAD artery. After giving rise to the PDA, the dominant RCA continues beyond the crux cordis (the junction of the atrioventricular and interventricular grooves) as the right posterior atrioventricular branch along the distal portion of the posterior (left) atrioventricular groove, terminating in one or several posterolateral branches that supply the diaphragmatic surface of the left ventricle. The RCA is nondominant in 15% of patients. One half of these patients have a left PDA and left posterolateral branches that are provided by the distal LCx artery (left dominant circulation). In such cases, the RCA is very small, terminates before reaching the crux, and does not supply any blood to the LV myocardium. The remaining patients have an RCA that gives rise to the PDA, with the LCx artery providing all of the posterolateral branches (balanced or codominant circulation). In approximately 25% of patients with RCA dominance, significant anatomic variations in the origin of the PDA have been documented. Such variations include partial supply of the PDA territory by acute marginal branches, double PDA, and early origin of the PDA proximal to the crux. At or near the crux, the dominant artery gives rise to a small atrioventricular node artery, which passes upward to supply the atrioventricular node.

Coronary Bypass Grafts. Selective cannulation of bypass grafts may be more challenging than cannulation of the native coronary arteries because the locations of graft ostia are more variable, even when surgical clips or ostia markers are used. Knowledge of the number, course, and type of bypass grafts obtained from the operative report is invaluable for identification of the location of the bypass grafts during angiography.

Saphenous Vein Grafts. SVGs from the aorta to the distal RCA or PDA originate from the right anterolateral aspect of the aorta approximately 5 cm superior to the sinotubular ridge. SVGs to the LAD artery (or diagonal branches) originate from the anterior portion of

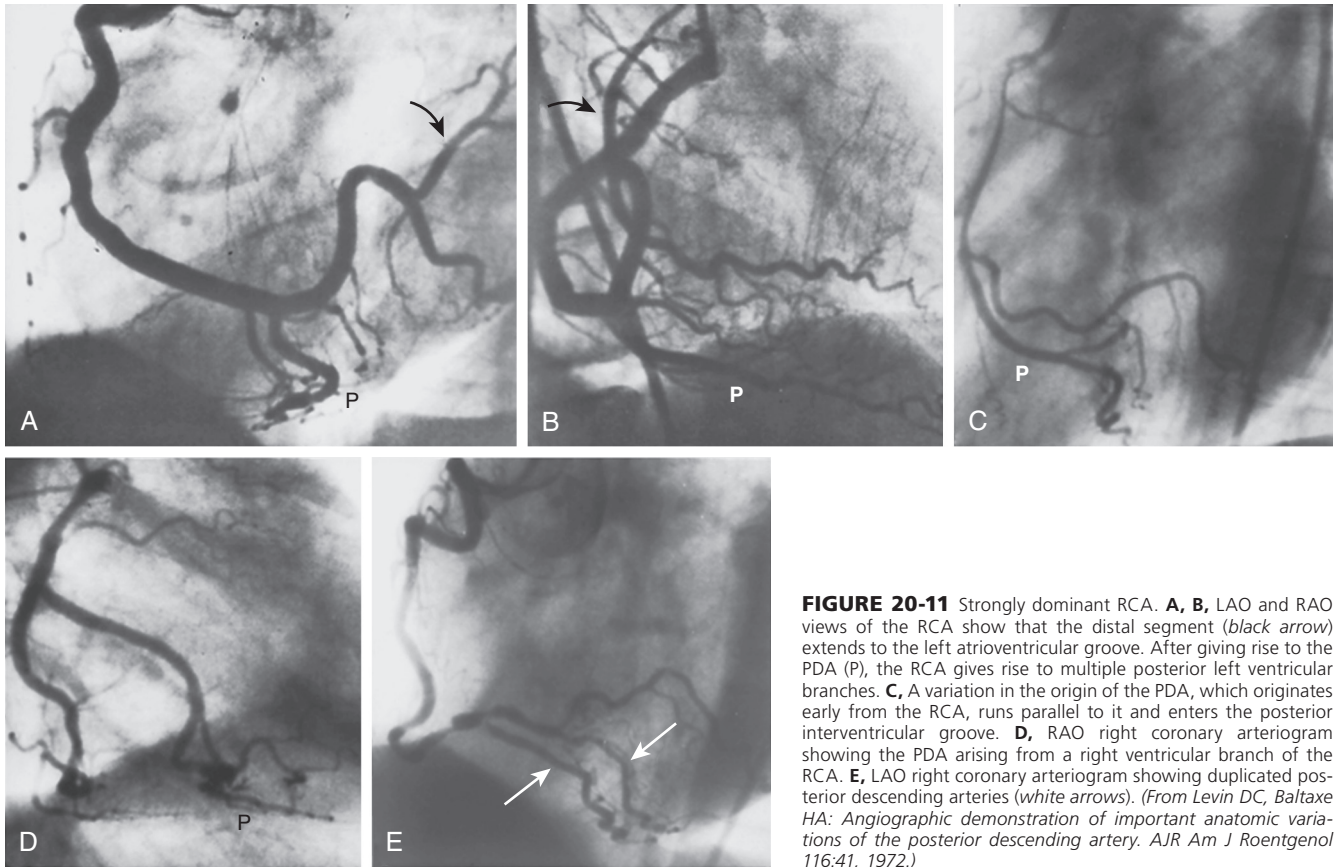

FIGURE 20-11 Strongly dominant RCA. **A, B**, LAO and RAO views of the RCA show that the distal segment (black arrow) extends to the left atrioventricular groove. After giving rise to the PDA (P), the RCA gives rise to multiple posterior left ventricular branches. **C**, A variation in the origin of the PDA, which originates early from the RCA, runs parallel to it and enters the posterior interventricular groove. **D**, RAO right coronary arteriogram showing the PDA arising from a right ventricular branch of the RCA. **E**, LAO right coronary arteriogram showing duplicated posterior descending arteries (white arrows). (From Levin DC, Baltaxe HA: Angiographic demonstration of important anatomic variations of the posterior descending artery. *AJR Am J Roentgenol* 116:41, 1972.)

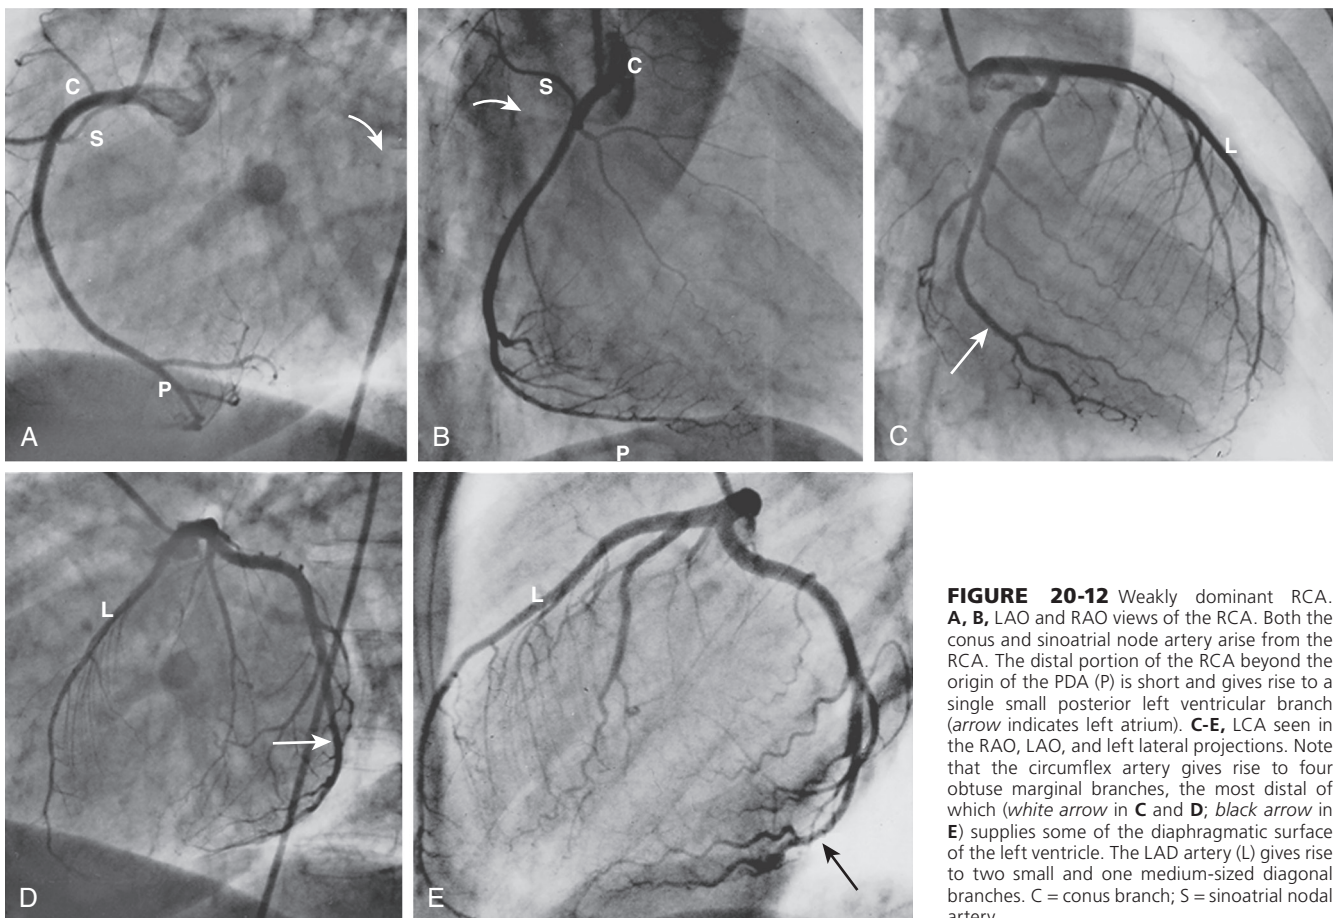

FIGURE 20-12 Weakly dominant RCA. **A, B**, LAO and RAO views of the RCA. Both the conus and sinoatrial node artery arise from the RCA. The distal portion of the RCA beyond the origin of the PDA (P) is short and gives rise to a single small posterior left ventricular branch (arrow indicates left atrium). **C-E**, LCA seen in the RAO, LAO, and left lateral projections. Note that the circumflex artery gives rise to four obtuse marginal branches, the most distal of which (white arrow in **C** and **D**; black arrow in **E**) supplies some of the diaphragmatic surface of the left ventricle. The LAD artery (L) gives rise to two small and one medium-sized diagonal branches. C = conus branch; S = sinoatrial nodal artery.

FIGURE 20-13 Dominant left coronary system. **A**, The LAO projection shows that the RCA is small and terminates before reaching the crux. **B-D**, The RAO, LAO, and left lateral projections show that the left circumflex artery is large and gives rise to the PDA (P) at the crux of the heart and to several posterior descending arteries. Arrows in **C** indicate posterolateral branches. L = LAD artery.

the aorta approximately 7 cm superior to the sinotubular ridge. SVGs to the obtuse marginal branches arise from the left anterolateral aspect of the aorta 9 to 10 cm superior to the sinotubular ridge. In most patients, all SVGs can be engaged with a single catheter, such as a Judkins right 4.0 or a modified Amplatz right 1 or 2. Other catheters useful for engaging SVGs include the right and left bypass graft catheters. Amplatz left 1 and 2 catheters are useful for superiorly oriented SVGs. A multipurpose catheter also may be useful for the cannulation of the downward takeoff SVG to the RCA or PDA.

Viewed in the LAO projection, the Judkins right 4 or Amplatz right 2 catheter rotates anteriorly from the leftward position as it is rotated in a clockwise direction. Observing the relation between the movement of catheter shaft at the femoral artery and the response of catheter tip on fluoroscopy will immediately indicate whether the catheter tip is anteriorly positioned in the aorta and likely to enter an SVG ostium or posteriorly positioned and unlikely to engage an SVG. Steady advancement and withdrawal of the catheter tip proximal and distal in the ascending aorta, 5 to 10 cm above the sinotubular ridge, with various degrees of rotation, usually result in entry into the SVG. Entry into the SVG is associated with abrupt outward motion of the tip of the catheter. When this occurs, a small test injection of contrast material will verify that the catheter is in the SVG. A well-circumscribed "stump" is almost always present if the SVG is occluded. Each SVG or stump must be viewed in nearly orthogonal views. Observation of the relation between the origin of the SVGs and surgical clips will confirm whether all targeted SVGs have been visualized. If neither a patent SVG nor a stump can be located, it may be necessary to perform an ascending aortogram (preferably in biplane) in an attempt to visualize all SVGs and their course to the coronary arteries.

The goal of SVG angiography is to assess the ostium of the SVG, its entire course, and the distal insertion ("touchdown") site at the anastomosis between the bypass SVG and the native coronary vessel. The ostium of the SVG must be evaluated by achieving a coaxial engagement of the catheter tip and the origin of the SVG. The body of the SVG must be evaluated with complete filling of the SVG by contrast material; inadequate opacification produces an angiographic artifact suggestive of friable filling defects. It is critical to assess the SVG insertion or anastomotic site in full profile without any overlap of the distal SVG or the native vessel. Angiographic assessment of the native vessels beyond SVG anastomotic sites requires views that are conventionally used for the native segments themselves. Sequential grafts are those that supply two different epicardial branches in a side-to-side fashion (for the more proximal epicardial artery) and terminate in an end-to-side anastomosis (for the more distal epicardial artery). A Y graft is characterized by a proximal anastomosis in an end-to-side fashion to another saphenous vein or arterial graft with two distal end-to-side anastomoses to the two epicardial grafts from these two grafts.

Internal Mammary Artery Grafts. The left IMA arises inferiorly from the left subclavian artery approximately 10 cm from its origin. Catheterization of the left IMA is performed using a specially designed J-tip IMA catheter (see Fig. 20-2, bottom row). The catheter is advanced into the aortic arch distal to the origin of the left subclavian artery in the LAO projection and then rotated counterclockwise and is gently withdrawn with the tip pointing in a cranial direction, allowing entry into the left subclavian artery (Fig. 20-14). A 0.035 J-tip or angled Terumo guidewire is advanced to the left subclavian artery under fluoroscopic guidance, and the catheter is advanced into the subclavian artery. The RAO or AP projection then can be used to cannulate the IMA selectively by withdrawing and slightly rotating the catheter anteriorly (counterclockwise) with the tip down. The right IMA also can be cannulated with the IMA catheter. The innominate artery is entered as visualized in the LAO projection, and the guidewire is advanced cautiously to avoid entry into the right common carotid artery. When the guidewire is positioned in the distal right subclavian artery, the IMA catheter is advanced to a point distal to the expected origin of the right IMA. The catheter is withdrawn in the LAO view and rotated to cannulate the right IMA.

The IMA itself is rarely affected by atherosclerosis. Angiographic studies of the IMAs should assess not only the patency of the graft itself but also the distal anastomosis, where most IMA graft compromise occurs. Although the LAO cranial view may be limited in its ability to demonstrate the anastomosis of the IMA and the LAD artery because of vessel overlap, the left lateral or AP cranial projection usually provides adequate visualization of the left IMA-LAD artery anastomotic site. The risk of catheter-induced dissection of the origin of the IMA can be reduced by careful manipulation of the catheter tip and avoidance of forceful advancement without the protection of the guidewire. If the IMA cannot be selectively engaged because of tortuosity of the subclavian artery, nonselective arteriography can be enhanced by placing a blood pressure cuff on the ipsilateral arm and inflating it to a pressure above systolic arterial pressure. Alternatively, the ipsilateral brachial or radial artery may be used to facilitate coaxial IMA engagement. IMA spasm can be treated with 50 to 200 μ g of intra-arterial nitroglycerin or 50 to 100 μ g of intra-arterial verapamil.

FIGURE 20-14 Catheterization of the IMA. The IMA is positioned in the aortic arch and visualized in the LAO projection. The catheter tip is rotated so that it engages the origin of the left subclavian artery immediately subjacent to the head of the clavicle (**A**). This is followed by gentle advancement of the guidewire into the left subclavian artery to a point distal to the origin of the left IMA. After the guidewire is removed, the left subclavian artery is visualized in the RAO projection, the catheter is withdrawn, and the catheter tip engages the ostium of the left IMA selectively (**B**). (From Judkins MW: *Coronary arteriography*. In Douglas JS Jr, King SB III [eds]: *Coronary Arteriography and Intervention*. New York, McGraw-Hill, 1985, p 231.)

The patient may feel chest warmth or discomfort on administration of contrast material because of injection into small IMA branches supplying the chest wall.

Gastroepiploic Artery. The right gastroepiploic artery (GEA) is the largest terminal artery of the gastroduodenal artery and was briefly used as an alternative in situ arterial conduit to the PDA in patients undergoing CABG. The gastroduodenal artery arises from the common hepatic artery in 75% of cases, but it may also arise from the right or left hepatic artery or the celiac trunk. Catheterization of the right GEA is carried out by first entering the common hepatic artery with a cobra catheter (**Fig. 20-15**). A torquable, hydrophilic-coated guidewire is advanced to the gastroduodenal artery and then to the right GEA. The cobra catheter is then exchanged for a multi-purpose or Judkins right coronary catheter, which then permits selective arteriography of the right GEA.

Standardized Projection Acquisition

Although general recommendations can be made for sequences of angiographic image acquisition that are applicable in most patients, tailored views may be needed to accommodate individual variations in anatomy. As a general rule, each coronary artery should be visualized using a number of different projections that minimize vessel foreshortening and overlap (**Fig. 20-16**). An AP view with shallow caudal angulation often is obtained first, to evaluate the possibility of LMCA disease. Other important views include the LAO cranial view to evaluate the middle and distal portions of the LAD artery, for which leftward positioning of the image intensifier should be sufficient to

FIGURE 20-15 Catheterization of the right gastroepiploic artery (GEA) graft. **A**, The celiac trunk (CT) is selectively engaged with a cobra catheter, and a guidewire is gently advanced to the gastroduodenal artery (GDA) and the GEA. **B**, The catheter is advanced over the guidewire for selective arteriography of the GEA graft. CHA = common hepatic artery; SA = splenic artery.

FIGURE 20-16 Importance of orthogonal projections. Each vascular segment of the coronary artery must be recorded in two orthogonal or nearly orthogonal views to avoid missing important diagnostic information about eccentric stenoses. In plane A, the image is associated with 75% stenosis, but in plane B, the image shows only 15% stenosis.

allow separation of the LAD, diagonal branch, and septal branch; the LAO caudal view to evaluate the LMCA, origin of the LAD, and proximal segment of the LCx; the RAO caudal view to assess the LCx and marginal branches; and a shallow RAO or AP cranial view to evaluate the midportion and distal portion of the LAD. The RCA should be visualized in at least two views, including an LAO cranial view that demonstrates the RCA and origin of the PDA and posterolateral branches and an RAO view that demonstrates the mid-RCA and proximal, middle, and distal termination of the PDA. An AP cranial projection also may be useful for the demonstration of the distal termination of the RCA, and a left lateral view is useful to visualize the ostium of the RCA and midportion of the RCA with separation of the RCA and its right ventricular branches.

Congenital Anomalies of the Coronary Circulation

Coronary artery anomalies are defined as those angiographic findings in which the number, origin, course, and termination of these arteries are rarely encountered in the general population. Coronary anomalies may occur in 1% to 5% of patients undergoing coronary arteriography, depending on the threshold for defining an anatomic variant^{43,44} (Table 20-7).

TABLE 20-7 Incidence of Coronary Anomalies in 1950 Angiograms

VARIABLE	NUMBER	FREQUENCY (%)
Coronary anomalies	110	5.64
Split RCA	24	1.23
Ectopic RCA (right cusp)	22	1.13
Ectopic RCA (left cusp)	18	0.92
Fistulas	17	0.87
Absent left main coronary artery	13	0.67
LCx arising from right cusp	13	0.67
LCA arising from right cusp	3	0.15
Low origin of RCA	2	0.1
Other anomalies	3	0.15

From Angelini P (ed): *Coronary Artery Anomalies: A Comprehensive Approach*. Philadelphia, Lippincott Williams & Wilkins, 1999, p 42.

The major reason for appropriate identification and classification of coronary anomalies is to determine their propensity for development of fixed or dynamic myocardial ischemia and sudden cardiac death, particularly in young and otherwise healthy persons.⁴⁵ Documentation of precise ischemia risk for some of these anomalies by conventional exercise stress testing or intravascular Doppler flow studies is poorly predictive, and these tests may fail to detect significant anatomic abnormalities.⁴⁶ Accordingly, coronary artery anomalies are divided into those that cause and those that do not cause myocardial ischemia (Table 20-8). Malignant features of anomalous coronaries include a slitlike ostium, an acute angle of takeoff, an intramural course, and significant compression between the aorta and the pulmonary trunk.⁴⁷

Anomalous Pulmonary Origin of the Coronary Arteries

With anomalous pulmonary origin of the coronary arteries (APOCA), these vessels arise from the pulmonary artery. The most common variant of this syndrome is an anomalous origin of the LCA from the pulmonary artery (ALCAPA),⁴⁸ although single-vessel origins of the RCA, LCx, or LAD from the pulmonary artery also have been reported. Untreated, and in the absence of an adequate collateral network, most infants with APOCA (95%) die within the first year. In the presence of an extensive collateral network, patients may survive into adulthood. Aortography typically shows a large RCA with absence of a left coronary ostium in the left aortic sinus. During the late phase of the aortogram, patulous LAD and LCx branches fill by means of collateral circulation from RCA branches. Still later in the filming sequence, retrograde flow from the LAD and LCx arteries opacifies the LMCA and its origin from the main pulmonary artery (Fig. 20-17). Once it is detected, CABG is recommended because of

TABLE 20-8 Ischemia Occurring in Coronary Anomalies

TYPE OF ISCHEMIA	CORONARY ANOMALY
Absence of ischemia	Most anomalies (split RCA, ectopic RCA from right cusp, ectopic RCA from left cusp)
Episodic ischemia	Anomalous origin of a coronary artery from the opposite sinus (ACAOS); coronary artery fistulas; myocardial bridge
Obligatory ischemia	Anomalous left coronary artery from the pulmonary artery (ALCAPA); coronary ostial atresia or severe stenosis

Modified from Angelini P (ed): *Coronary Artery Anomalies: A Comprehensive Approach*. Philadelphia, Lippincott Williams & Wilkins, 1999, p 42.

FIGURE 20-17 Anomalous origin of the LCA from the pulmonary artery. **A-C**, The thoracic aortogram shows a large RCA and no anterograde filling of the LCA. The LCA fills primarily through extensive collaterals from the RCA to the LAD artery (black arrow in all images). The anomalous origin of the LCA from the pulmonary artery is demonstrated in late phases of the aortogram (**C**, curved white arrow).

the high incidence of sudden death, cardiomyopathy, and arrhythmias associated with APOCA.

Anomalous Coronary Artery from the Opposite Sinus

With the entity termed anomalous coronary artery from the opposite sinus (ACAOS), origin of the LCA from the proximal RCA or the right aortic sinus with subsequent passage between the aorta and the right ventricular outflow tract has been associated with sudden death during or shortly after exercise in young persons⁴⁹⁻⁵¹ (Figs. 20-18 to 20-20). The increased risk of sudden death may be due to a slitlike ostium, a bend with acute takeoff angles of the aberrant coronary arteries, or arterial compression between the pulmonary trunk and aorta when blood flow through these vessels increases with exercise and stress. Origin of the RCA from the LCA or left aortic sinus with passage between the aorta and the right ventricular outflow tract also is associated with myocardial ischemia and sudden death. In rare cases of anomalous origin of the LCA from the right sinus, myocardial ischemia may occur even if the LCA passes anterior to the right ventricular outflow tract or posterior to the aorta (i.e., not through a tunnel between the two great vessels). Although CABG has been the traditional revascularization approach in patients with ACAOS, coronary stenting also has been reported to yield acceptable medium-term success.

The course of the anomalous coronary arteries is easily assessed by angiography in the RAO view. The four common courses for the anomalous LCA arising from the right sinus of Valsalva are septal, anterior, interarterial, and posterior. The posterior course of the anomalous LCA arising from the right sinus of Valsalva is similar to the course of the anomalous LCx artery arising from the right sinus of Valsalva (see Fig. 20-19), whereas the common interarterial course of the anomalous RCA from the left sinus of Valsalva is similar to the interarterial course of the anomalous LCA arising from the right sinus of Valsalva.

When either the LCA or the LAD artery arises anomalously from the right sinus, another angiographic method to identify the course of the anomalous vessel is to pass a catheter into the main pulmonary artery and then perform an arteriogram of the aberrant coronary artery in the steep AP caudal projection. This view places the aberrant coronary artery, the rightward and anterior pulmonary valve, and the leftward and posterior aortic valve all in one plane. From this "laid-back" aortogram, which can be used even in mapping the course of anomalous coronary arteries in transposition of the great vessels, it usually is possible to confirm whether the course of the aberrant coronary artery is between the great vessels. Although angiography is useful to establish the presence of anomalous coronary arteries, coronary computed tomography angiography

FIGURE 20-18 Four possible pathways of the anomalous LCA arising from the right coronary sinus: **A**, interarterial, between the aorta and the pulmonary artery (PA); **B**, retroaortic; **C**, prepulmonic; and **D**, septal, beneath the right ventricular outflow tract. **E**, Computed tomography angiography image shows the LCA taking a prepulmonic course (arrows), passing anterior to the pulmonary artery (PA). **F**, The LAD artery arises from the right coronary sinus and takes a septal (subpulmonic) course. The RCA has a normal origin from the right coronary sinus (curved arrow), but the LAD artery arises from the right coronary cusp and courses beneath the pulmonary artery (straight arrow). **G**, Computed tomography angiography image shows the left circumflex coronary artery (shorter straight arrow) arising from its normal location in the left coronary sinus. The aberrant LAD artery arises from the right coronary sinus and takes a subpulmonic course (longer straight arrow). A = aorta; L = left coronary sinus; N = noncoronary sinus; R = right coronary sinus. (From Kim SY, Seo JB, Do KH, et al: Coronary artery anomalies: classification and ECG-gated multi-detector row CT findings with angiographic correlation. *Radiographics* 26:317, 2006.)

FIGURE 20-19 Anomalous origin of the LCx artery from the right coronary sinus. **A**, The LAD artery arises from the left coronary sinus in the usual location, but the LCx artery is absent. **B**, A left ventriculogram in the RAO projection shows the “button sign” (*arrow*) of the anomalous LCx artery coursing behind the aorta. **C**, Computed tomography angiography image shows the origin of the LCx artery from the right coronary sinus and passing behind the aorta (*A*, *arrow*). **D**, **E**, Angiographic demonstration of the anomalous LCx artery (*arrows*) from the right coronary sinus shown in the LAO (**D**) and the RAO (**E**) projections. PA = pulmonary artery.

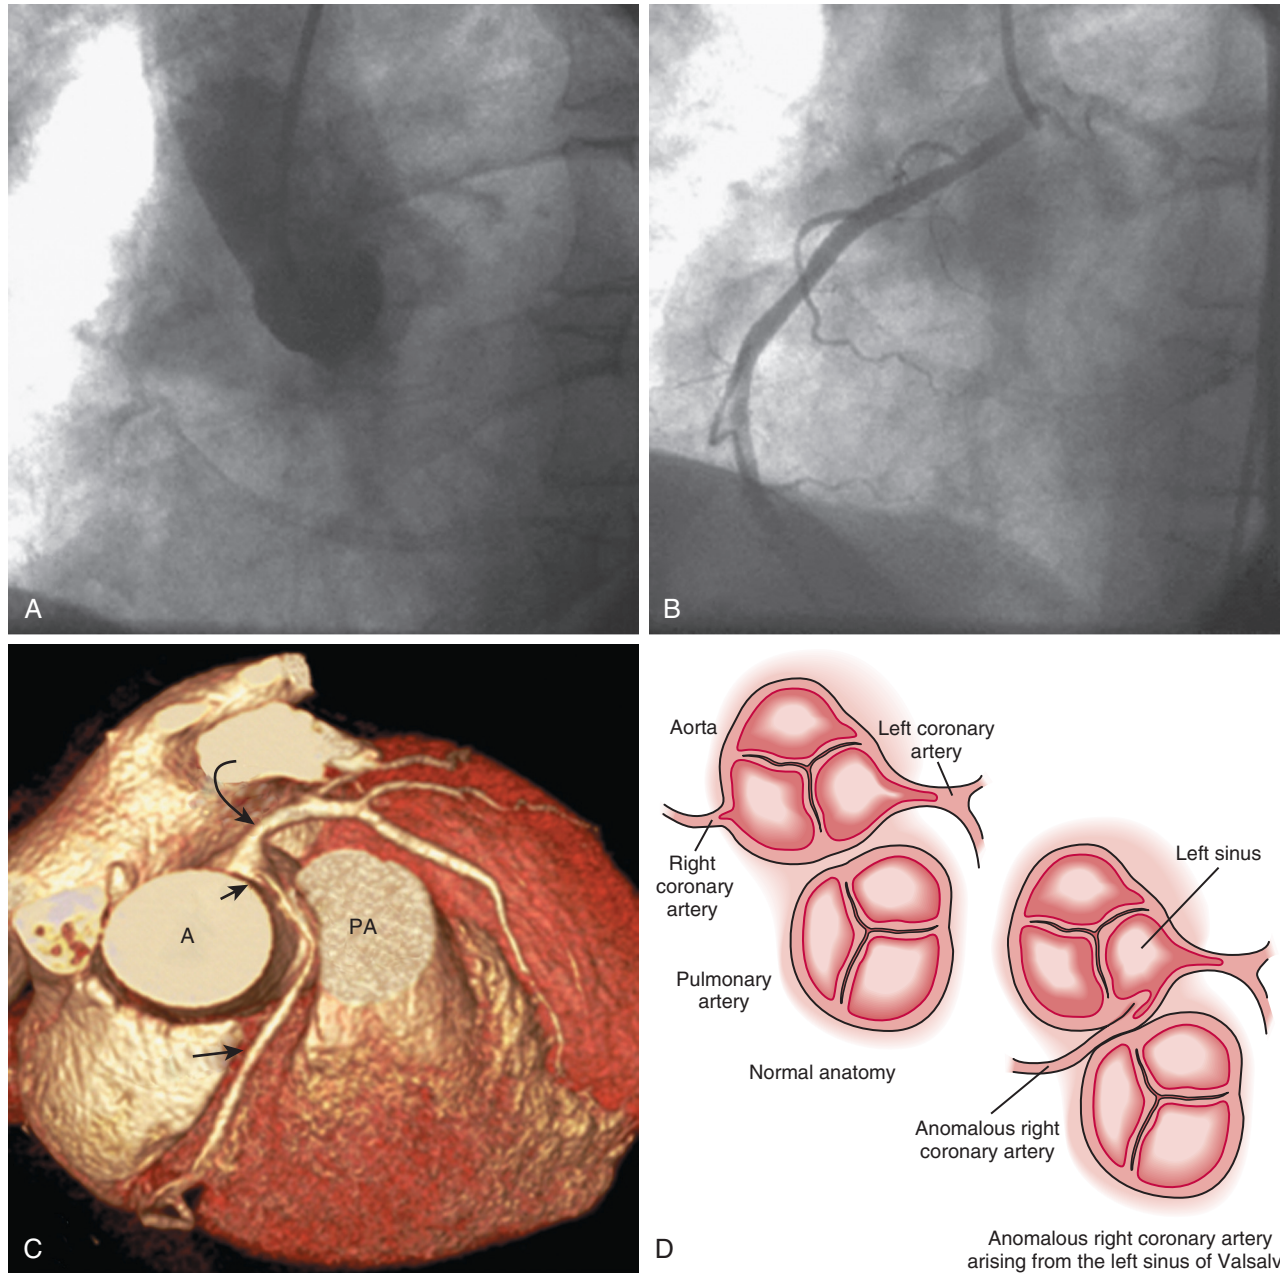

FIGURE 20-20 Anomalous origin of the RCA from the left coronary sinus. **A**, An aortogram in left oblique projection shows the absence of the right coronary artery from the right coronary sinus. **B**, Selective injection of the RCA from the left coronary sinus. **C**, Computed tomography angiography image shows the slitlike origin of the RCA (straight arrow) from the left coronary sinus and the normal origin of the LCA (curved arrow). The RCA courses between the aorta (A) and pulmonary artery (PA). **D**, Left: Normal anatomy of the RCA and LCA. Right: The anomalous origin of the RCA is shown coursing between the aorta and the pulmonary artery. (From Kim SY, Seo JB, Do KH, et al: Coronary artery anomalies: Classification and ECG-gated multi-detector row CT findings with angiographic correlation. *Radiographics* 26:317, 2006; and Qayyum U, Leya F, Steen L, et al: New catheter design for cannulation of the anomalous right coronary artery arising from the left sinus of Valsalva. *Catheter Cardiovasc Interv* 60:382, 2003.)

(see Chapter 18) also may be an important adjunctive diagnostic tool to establish the course of the vessels.⁵²

Coronary Artery Fistulas

Coronary artery fistula is defined as an abnormal communication between a coronary artery and a cardiac chamber or major vessel such as the vena cava, right or left ventricle, pulmonary vein, or pulmonary artery.^{53,54} Coronary artery fistula is a rare finding, involving the RCA or its branches in approximately half of the cases, and drainage generally occurs into the right ventricle, right atrium, and pulmonary arteries (Figs. 20-21 to 20-23). Coronary arteriography is the best method for demonstration of the origin of these fistulas.

The clinical presentation associated with coronary artery fistula is dependent on the type of fistula, shunt volume, site of the shunt, and presence of other cardiac conditions, although patients (50%) often

remain asymptomatic.⁵³ Dyspnea on exertion, fatigue, congestive heart failure, pulmonary hypertension, bacterial endocarditis, and arrhythmias are common presentations in symptomatic patients. Myocardial ischemia also may occur, but the mechanism remains speculative.⁵³ Symptomatic patients or those with severe shunts may be treated with surgical shunt closure, although percutaneous closure with coil embolization also may be tried.

Congenital Coronary Stenosis or Atresia

Congenital stenosis or atresia of a coronary artery can occur as an isolated lesion or in association with other congenital diseases, such as calcific coronary sclerosis, supraaortic stenosis, homocystinuria, Friedreich ataxia, Hurler syndrome, progeria, and rubella syndrome. In such cases, the atretic vessel usually fills by means of collateral circulation from the contralateral side.

FIGURE 20-21 Congenital fistula to the left ventricle. **A**, RAO cranial view of the left coronary arteriogram shows a congenital fistula (arrow) arising from branches of both the LAD and LCx arteries and draining into the left ventricle. **B**, LAO view of the left coronary arteriogram shows the fistula (arrow).

FIGURE 20-22 Congenital fistula to the pulmonary artery. The left coronary arteriogram shows a congenital fistula arising from the LAD (large arrow) and terminating (small arrow) in the pulmonary artery demonstrated in the RAO (**A**) and LAO (**B**) views, the latter with caudal angulation.

Myocardial Bridging

The three major coronary arteries generally course along the epicardial surface of the heart. On occasion, however, short coronary artery segments descend into the myocardium for a variable distance. This abnormality, termed *myocardial bridging*, occurs in 5% to 12% of patients and usually is confined to the LAD artery⁵⁵ (**Fig. 20-24**). Because a “bridge” of myocardial fibers passes over the involved segment of the LAD, each systolic contraction of these fibers can cause narrowing of the artery. Myocardial bridging has a characteristic appearance on angiography; the bridged segment is of normal caliber during diastole and abruptly narrows with each systole. Although bridging is not thought to be of any hemodynamic significance in most cases, myocardial bridging has been associated with angina, arrhythmia, depressed LV function, myocardial stunning, early death after cardiac transplantation, and sudden death.^{55,56} Intracoronary Doppler studies have shown that diastolic flow abnormalities may be present in patients with myocardial bridging.⁵⁵ Medical treatment generally includes beta blockers, although nitrates should be avoided because they may worsen symptoms. Intracoronary artery stenting and surgery have been attempted in selected patients, but the results have been mixed.⁵⁵

High Anterior Origin of the Right Coronary Artery

High anterior origin of the right coronary artery is a commonly encountered anomaly that is of no hemodynamic significance. The

inability to engage the ostium of the RCA selectively by conventional catheter manipulation raises the possibility of this superior origin of the RCA above the sinotubular ridge. Forceful, nonselective injection of contrast medium into the right sinus of Val-salva may reveal the anomalous takeoff of the RCA, which can then be selectively engaged with a Judkins right 5.0 catheter or an Amplatz left 1.0 or 2.0 catheter.

Coronary Artery Spasm

Coronary artery spasm is defined as a dynamic and reversible occlusion of an epicardial coronary artery caused by focal constriction of the smooth muscle cells within the arterial wall (see **Chapter 49**). Initially described by Prinzmetal and colleagues (Prinzmetal or variant angina) in 1959, this form of angina was not provoked by the usual factors, such as exercise, emotional upset, cold, or ingestion of a meal. Cigarette smoking, cocaine use, alcohol, intracoronary irradiation, and administration of catecholamines can induce coronary artery spasm during general anesthesia (see **Chapters 53 and 54**). Although the ST-segment elevation often is striking, this ECG feature rapidly reverts to normal when the pain disappears spontaneously or is terminated by the administration of nitroglycerin (**Figs. 20-25 and 20-26**). Coronary artery spasm may be accompanied by atrioventricular block, ventricular ectopic activity, ventricular tachycardia, or ventricular fibrillation. MI and death are rare manifestations of coronary artery spasm. Coronary artery spasm also can be superimposed on the presence of an intramyocardial bridge. On rare occasions, velocity of

coronary flow may be reduced in the absence of a fixed coronary obstruction or coronary vasospasm.

Coronary arteriography is useful in patients with suspected coronary artery spasm to exclude the presence of concomitant CAD and to document an episode of coronary artery spasm by use of provocative intravenous medications or maneuvers. Three provocative tests can be performed to detect the presence of coronary artery spasm. Intravenous ergonovine maleate can elicit two types of responses: A diffuse coronary vasoconstriction that occurs in all of the epicardial arteries is a physiologic response to ergonovine not diagnostic of coronary artery spasm. The second response to ergonovine is a focal, occlusive spasm of the epicardial artery that is associated with chest pain and ST-segment elevation. Nitroglycerin should be administered directly into the coronary artery to relieve the coronary spasm. A second provocative test is the use of intravenous acetylcholine. Although this test is more sensitive than ergonovine provocation, it may be less specific because of the positive response in patients with atherosclerotic CAD. The final provocative test is for the patient to perform hyperventilation during coronary arteriography, which is less sensitive but highly specific for the presence of coronary artery spasm.

In the absence of a positive stimulation test result, the diagnosis of coronary artery spasm must rely instead on clinical features and response to treatment with nitrates and calcium channel blockers. Sole therapy with beta blockers should be avoided because it can worsen the occurrence of coronary artery spasm. Coronary artery spasm that is refractory to conventional therapy with long-acting calcium channel blockers and nitrates can be treated with coronary stenting.

Assessing Lesion Complexity

Heterogeneity of the composition, distribution, and location of atherosclerotic plaque within the native coronary artery results in unique patterns of stenosis morphology in patients with CAD. Criteria established by a joint American College of Cardiology/American Heart association (ACC/AHA) Task Force in the 1980s suggested that procedure success and complication rates were related to a number of lesion characteristics (**Table 20-9**). During two decades after the publication of these criteria, the most complex lesion morphologies (i.e., type C lesions) remained associated with reduced procedural success in patients with CAD⁵⁷ (**Table 20-10**).

Two additional risk scores were developed and compared with the ACC/AHA lesion complexity score: the Society for Cardiovascular Angiography and Interventions (SCAI) risk score and the Mayo Clinic Risk Score.^{58,59} The SCAI risk score used an ordinal ranking of two composite criteria, vessel patency and complex morphology, to classify lesions into four groups—non-type C patent, type C patent,

FIGURE 20-23 Iatrogenic fistula of the LAD artery in a patient who had previously undergone cardiac transplantation. The fistula developed between the LAD artery and the right ventricle after right ventricular biopsy (arrow).

FIGURE 20-25 Coronary artery spasm. Proximal and distal coronary artery spasm was found after stent placement in the LAD artery (**A**, arrows), which was relieved with intracoronary nitroglycerin (**B**).

FIGURE 20-24 Intramyocardial bridge. The LAD artery courses into the myocardium shown in diastole (**A**) and systole (**B**). Note compression of the lumen caliber of the artery during systole.

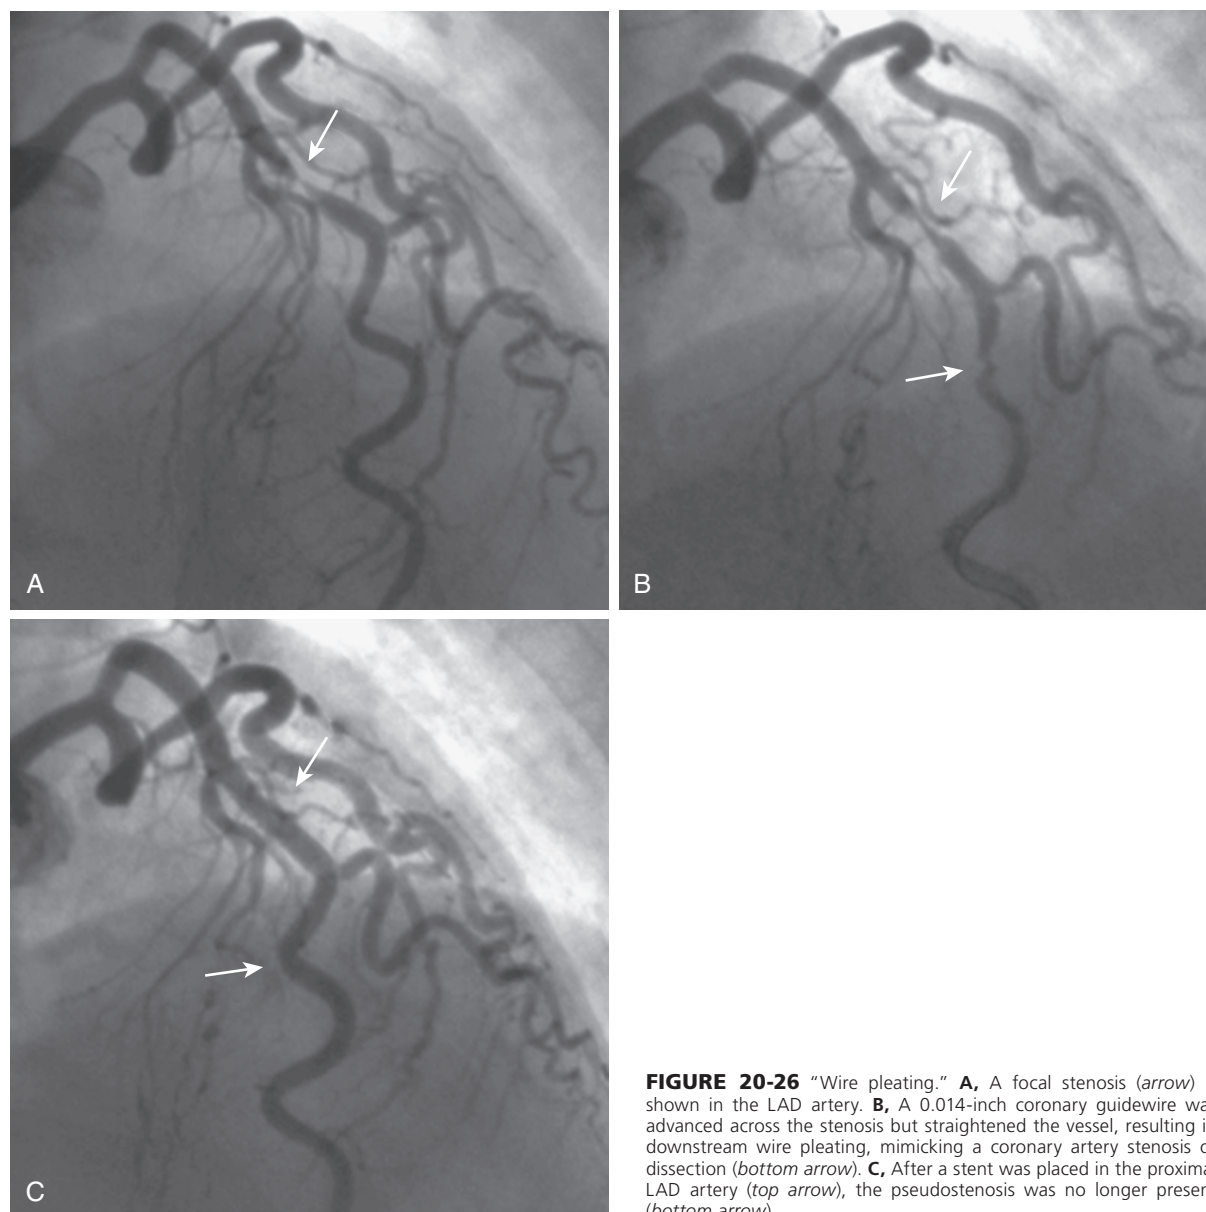

FIGURE 20-26 “Wire pleating.” **A**, A focal stenosis (arrow) is shown in the LAD artery. **B**, A 0.014-inch coronary guidewire was advanced across the stenosis but straightened the vessel, resulting in downstream wire pleating, mimicking a coronary artery stenosis or dissection (bottom arrow). **C**, After a stent was placed in the proximal LAD artery (top arrow), the pseudostenosis was no longer present (bottom arrow).

non-type C occluded, and type C occluded—to improve prediction of outcome.⁶⁰ The Mayo Clinic Risk Score added the integer scores for the presence of eight morphologic variables and provided a better risk stratification than that achieved with the ACC/AHA lesion classification for the prediction of cardiovascular complications.⁵⁹

The SYNTAX Score (see Chapters 54 and 55) quantitates the complexity and the extent of CAD to aid clinicians in assessing early and late outcomes after PCI and CABG in patients with multivessel CAD and has become the preferred risk assessment tool for grading lesion complexity.⁶¹⁻⁶³ Components of the SYNTAX Score include presence of up to 12 lesions with a greater than 50% diameter stenosis in vessels greater than 1.5 mm in diameter, with a multiplication factor of 2 for nonocclusive lesions and 5 for occlusive lesions, and weighting by its contribution to the myocardial bed that it supplies. Each lesion is assessed for its severity, presence of a total occlusion, side branches, and collaterals, and lesion complexity is weighted by multiple tandem lesions, aorto-ostial location, diffuse disease, severe tortuosity, length greater than 20 mm, heavy calcification, and thrombus.

The SYNTAX Score has been used to guide recommendations for revascularization with PCI or CABG⁶³ and has been modified to include patients with previous CABG.⁶⁴ Further modifications of the

SYNTAX Score have incorporated a functional assessment of lesions to improve the diagnostic accuracy of the SYNTAX Score. Incomplete revascularization using the SYNTAX Score has been correlated with a worse long-term outcome.⁵⁵ The SYNTAX Score II has added clinical variables to enhance decision making between CABG and PCI.⁶⁶ The SYNTAX Score may be expanded using noninvasive imaging (see Chapter 18).^{67,68}

Lesion Length

Lesion length may be measured by a number of methods, including measurement of the “shoulder-to-shoulder” extent of atherosclerosis narrowed by more than 20%, quantification of the lesion length more than 50% narrowed, and estimation of the distance between the proximal and distal angiographically “normal” segment; the last method is used most commonly in clinical practice and provides a longer length than more quantitative methods. Diffuse (>20 mm) lesions are associated with reduced procedural success with drug-eluting stents.

Degenerated Saphenous Vein Grafts

A serial angiographic study in patients undergoing CABG showed that 25% of SVGs undergo occlusion within the first year.⁶⁹ Although use

TABLE 20-9 Characteristics of Type A, B, and C Coronary Lesions

CHARACTERISTIC	DESCRIPTION
Type A Lesions (high success, >85%; low risk)	
Discrete (<10 mm)	Little or no calcium
Concentric	Less than totally occlusive
Readily accessible	Not ostial in locations
Nonangulated segment, <45 degrees	No major side branch involvement
Smooth contour	Absence of thrombus
Type B Lesions (moderate success, 60%-85%; moderate risk)	
Tubular (10 to 20 mm in length)	Moderate to heavy calcification
Eccentric	Total occlusions <3 months old
Moderate tortuosity of proximal segment	Ostial in location
Moderately angulated segment, ≥45 degrees, <90 degrees	Bifurcation lesion requiring double guidewire
Irregular contour	Some thrombus present
Type C Lesions (low success, <60%; high risk)	
Diffuse (>2 cm in length)	Total occlusion >3 months old
Excessive tortuosity of proximal segment	Inability to protect major side branches
Extremely angulated segments, ≥90 degrees	Degenerated vein grafts with friable lesions

From Ryan TJ, Bauman WB, Kennedy JW, et al: Guidelines for percutaneous coronary angioplasty. A report of the AHA/ACC Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures (Subcommittee on Percutaneous Transluminal Coronary Angioplasty). *Circulation* 88:2987, 1993.

of a drug-eluting stent may reduce the rate of recurrence caused by restenosis, only embolic protection devices have reduced the frequency of procedural complications⁷⁰ (see Chapter 55). The extent of graft degeneration and estimated volume of plaque in the target lesion are independent correlates of increased 30-day major adverse cardiac event rates.⁷¹

Coronary Calcification

Calcium deposition is a marker for atherosclerotic CAD (see Chapter 18). Coronary calcification is a diffuse and heterogeneous process that occurs in diseased coronary arteries, and in regions where coronary calcification is intraluminal and concentrically distributed, coronary stenoses become rigid and undilatable with use of conventional balloon angioplasty. Conventional angiography has only modest sensitivity in identifying coronary calcification and is less useful than intravascular ultrasound (IVUS) in detecting milder degrees of lesion calcification. Stent expansion may be compromised in extensively calcified coronary lesions, predisposing affected patients to stent thrombosis,⁷² restenosis,⁷³ and stent fracture.^{74,75} Adjunctive atheroablative methods, such as rotational atherectomy and cutting or scoring balloon angioplasty, often are useful to facilitate coronary dilation and stent expansion in heavily calcified lesions (see Chapter 55).⁷⁶

Thrombus

Contrast angiography is a relatively insensitive method for detection of coronary thrombus. The presence of coronary thrombus often identifies the site of acute plaque rupture in patients with an acute coronary syndrome, but it also may be seen in patients with thromboembolism caused by intracardiac thrombus, in those with spiculated coronary calcification,⁷⁷ and in those with generalized

prothrombotic states. Coronary thrombus is associated with a higher risk of complications during PCI, primarily relating to embolization of thrombotic debris into the distal circulation. With large, intracoronary thrombi, treatment with a combination of pharmacologic agents (e.g., glycoprotein IIb/IIIa inhibitors) and mechanical devices (e.g., passive aspiration and rheolytic thrombectomy) is recommended.⁷⁸

Total Occlusion

Total coronary occlusion is identified as an abrupt termination of the epicardial vessel; antegrade and retrograde collaterals may be present and are helpful in quantifying the length of the totally occluded segment. Success in passage of a coronary guidewire across the occlusion depends on the occlusion duration and on certain lesion morphologic features, such as bridging collaterals, occlusion length of more than 15 mm, and absence of a “nipple” to guide advancement of the guidewire. Total occlusion remains a major reason for referral of patients for CABG. The optimal technique for coronary revascularization is determined using four angiographic parameters: location of the proximal cap; length of the occluded segment; presence of branches, as well as size and quality, of the target vessel at the distal cap; and suitability of collaterals for retrograde techniques.⁷⁹ On the basis of these four characteristics, substantial improvement has been achieved in securing access to the coronary vessel.^{80,81}

Coronary Perfusion

Perfusion distal to a coronary stenosis can occur in an antegrade distribution by means of the native vessel, in retrograde fashion through collaterals, or through a coronary bypass graft with the flow rate influenced by the severity and complexity of the stenosis and the status of the microvasculature. The Thrombolysis in Myocardial Infarction (TIMI) study group established criteria to assess the degree of antegrade coronary reperfusion in patients with acute MI and found that complete restoration of antegrade perfusion by TIMI 3 flow was associated with the lowest mortality rate (Table 20-11), and these indices have been correlated with prognosis in patients with acute MI.^{41,82} TIMI frame count and the TIMI myocardial perfusion grade permit further quantification of antegrade flow and assessment of distal microvascular perfusion.⁸³

Coronary Collateral Circulation

Networks of small anastomotic branches interconnect the major coronary arteries and serve as precursors for the collateral circulation that maintains myocardial perfusion despite the development of severe proximal atherosclerotic narrowings. Collateral channels may not be seen in patients with normal or mildly diseased coronary arteries because of their small (<200 μm) caliber, but as the coronary disease progresses and becomes more severe (>90% stenosis), a pressure gradient is generated between the anastomotic channels and the distal vessel that is hypoperfused. The transstenotic pressure gradient facilitates blood flow through the anastomotic channels, which progressively dilate and eventually become visible as collateral vessels (Fig. 20-27).

The visible collateral channels arise from the contralateral coronary artery, from the ipsilateral coronary artery through intracoronary collateral channels, or through “bridging” channels that have a serpiginous course from the proximal coronary artery to the coronary artery distal to the occlusion. These collaterals may provide up to 50% of antegrade coronary flow in chronic total occlusion. Although collaterals provide some protection against myocardial necrosis with total coronary occlusion, this effect is incomplete, and myocardial necrosis may occur with collateralized total occlusion.⁸⁴ Grading of flow of collaterals can be accomplished using the Rentrop criteria: Rentrop grade 0 (no filling), Rentrop grade 1 (small side branches filled), Rentrop grade 2 (partial epicardial filling of the occluded artery), and Rentrop grade 3 (complete epicardial filling of the occluded artery).

**TABLE 20-10** Definitions of Preprocedural Lesion Morphology

FEATURE	FREQUENCY (%)	DEFINITION
Eccentricity	48.0	Stenosis that is noted to have one of its luminal edges in the outer quarter of the apparent normal lumen
Irregularity	17.9	Characterized by lesion ulceration, intimal flap, aneurysm, or sawtooth pattern
Ulceration	12.1	Lesions with a small crater consisting of a discrete luminal widening in the area of the stenosis
Intimal flap	3.22	A mobile, radiolucent extension of the vessel wall into the arterial lumen
Aneurysm	5.49	Segment of arterial dilation larger than the dimensions of the normal arterial segment
Sawtooth	0.84	Multiple, sequential stenosis irregularities
Length		Measured "shoulder to shoulder" in an unforeshortened view
Discrete	55.0	Lesion length <10 mm
Tubular	34.8	Lesion length 10-20 mm
Diffuse	10.2	Lesion length >20 mm
Ostial location	10.0	Origin of the lesion within 3 mm of the vessel origin
Angulation		Vessel angle formed by the center line through the lumen proximal and distal to the stenosis
Moderate	15.3	Lesion angulation ≥ 45 degrees
Severe	0.93	Lesion angulation ≥ 90 degrees
Bifurcation stenosis	6.05	Stenosis involving the parent and daughter branch if a medium or large branch (>1.5 mm) originates within the stenosis and if the side branch is completely surrounded by stenotic portions of the lesion to be dilated
Proximal tortuosity		
Moderate	15.3	Lesion is distal to two bends >75 degrees
Severe	NR	Lesion is distal to three bends >75 degrees
Degenerated SVG	7.1	Graft characterized by luminal irregularities or ectasia constituting >50% of the graft length
Calcification	34.3	Readily apparent densities noted within the vascular wall visible at the site of the stenosis
Total occlusion	6.4	TIMI 0 or 1 flow
Thrombus	3.4	Discrete, intraluminal filling defect is noted with defined borders and is largely separated from the adjacent wall; contrast staining may or may not be present

NR = not reported; SVG = saphenous vein graft; TIMI = Thrombolysis in Myocardial Infarction.

*Data obtained from 846 lesions undergoing qualitative angiographic analysis at the Washington Hospital Center Angiographic Core Laboratory.

TABLE 20-11 Thrombolysis in Myocardial Infarction (TIMI) Flow

TIMI FLOW	DESCRIPTION
Grade 3 (complete reperfusion)	Anterograde flow into the terminal coronary artery segment through a stenosis is as prompt as anterograde flow into a comparable segment proximal to the stenosis. Contrast material clears as rapidly from the distal segment as from an uninvolved, more proximal segment.
Grade 2 (partial reperfusion)	Contrast material flows through the stenosis to opacify the terminal artery segment. However, contrast material enters the terminal segment perceptibly more slowly than more proximal segments. Alternatively, contrast material clears from a segment distal to a stenosis noticeably more slowly than from a comparable segment not preceded by a significant stenosis.
Grade 1 (penetration with minimal artery perfusion)	A small amount of contrast material flows through the stenosis but fails to opacify fully beyond the area of obstruction.
Grade 0 (no perfusion)	No contrast flows through the stenosis.

Modified from Sheehan F, Braunwald E, Canner P, et al: The effect of intravenous thrombolytic therapy on left ventricular function: A report on the tissue-type plasminogen activator and streptokinase from the Thrombolysis in Myocardial Infarction (TIMI Phase I) trial. *Circulation* 75:817, 1987.

Quantitative Angiography

Visual estimations of coronary stenosis severity are used by virtually all clinicians to guide clinical practice, although these "eyeball" estimates are limited by substantial observer variability and bias and an overestimation of stenosis severity by almost 10% compared with quantitative measurements.⁸⁵ More reliable and objective "online" quantitative coronary measurements have had limited clinical use and have been largely supplanted by more physiologic measures of stenosis severity, such as direct measurements of fractional and coronary flow reserve in regions of intermediate (40% to 70%) stenosis

severity (see Chapters 49 and 55).⁸⁶ A number of angiographic measures have been developed to more quantitatively assess early and late procedural outcome after PCI for research protocols and registry reports (Table 20-12).

Quantitative coronary angiography initially was performed by Greg Brown and colleagues at the University of Washington more than 30 years ago. Hand-drawn arterial contours corrected for pincushion distortion were reconstructed to represent a three-dimensional arterial contour; reference vessel and minimal lumen diameters were measured. These initial quantitative angiographic methods were

FIGURE 20-27 Coronary collaterals. **A**, A Kugel branch arises from the proximal RCA and extends to the distal posterior descending branch of the RCA (arrow). **B**, Bridging collaterals (arrow) connecting the proximal and distal segments of the RCA. **C**, A microchannel in the mid-LAD artery (arrow). **D**, A Vieussens collateral extends from the proximal RCA to the LAD artery (arrow).

time-consuming and cumbersome and have now been largely replaced with computer-assisted methods for automated arterial contour detection that have used improved microprocessor speed and storage capacity.

Quantitative analysis of digital angiograms is divided into two distinct processes: image calibration and arterial contour detection. *Image calibration* is accomplished using the contrast-filled diagnostic or guiding catheter as a scaling device, yielding a calibration factor in millimeters per pixel. Mapping of *arterial contours* begins by drawing a center line through the segment of interest. Linear density profiles are then constructed perpendicular to the center line, and a weighted average of the first and second derivative functions is used to define the catheter or arterial edges. Individual edge points are then connected using an automated algorithm, and outliers are discarded and the edges are smoothed. The automated algorithm is then applied to a selected arterial segment, and absolute coronary dimensions and percent diameter stenosis are obtained. Novel quantitative algorithms have been developed for the measurement of smaller vessels, to assess bifurcation lesions, and to facilitate three-dimensional reconstruction.^{87,88}

Angiographic success is defined as a less than 50% residual diameter stenosis after balloon angioplasty or less than 20% diameter stenosis after coronary stent placement (see Chapter 55). Long-term results after PCI are described using binary angiographic restenosis, defined as 50% or greater follow-up diameter stenosis, and late lumen loss, defined as the loss in lumen diameter during the intermediate (6- to 9-month) follow-up period. The identification of the maximal

reference diameter by quantitative angiography also has been useful in selecting the size of bioresorbable scaffolds for ensuring apposition to the vessel wall.^{89,90}

PITFALLS OF CORONARY ARTERIOGRAPHY

Coronary arteriography has several important limitations, including substantial interobserver variability, lack of correlation with functional measures with intermediate (40% to 70%) stenoses, and the inability to identify vulnerable plaque lesions that may be predisposed to rupture. Certain technical factors also can be mitigated at the time of image acquisition to improve the interpretations of the coronary arteriogram and guide therapeutic approaches.⁴

Inadequate Vessel Opacification. Inadequate filling of the coronary artery with contrast medium results in incomplete vessel opacification or “streaming,” which may misrepresent the degree of ostial and side branch disease and overestimate the amount of thrombus or the stenosis severity. The causes of contrast streaming include increased native coronary blood flow in the setting of LV hypertrophy, aortic insufficiency, or anemia; competitive filling from collateral branches or bypass graft conduits; diagnostic catheter positioning that is not coaxial (or “in line”) with the coronary ostium; use of a smaller (4F) injection catheter; and dislodgment of the diagnostic catheter during injection of the contrast agent. Contrast streaming can be overcome by a more forceful injection of the contrast agent so long as catheter tip position and pressure recording confirm the safety of such a maneuver. Switching to an angioplasty-guiding catheter

with a soft, short tip and a larger lumen than that of a diagnostic catheter may allow more complete opacification of the target coronary artery or bypass graft. Superselective injection of contrast medium into the LCx (or LAD) artery through a short LMCA may give the impression of total occlusion of the LAD (or LCx).

Eccentric Stenoses. By its nature, coronary atherosclerosis is a ubiquitous process that leads to asymmetric plaque distribution within the coronary artery. Although most segments of the artery wall are involved in the atherosclerotic process, eccentric or slitlike lesions may be seen by angiography in regions of more focal plaque accumulation. The hemodynamic significance of eccentric lesions is dependent on the percentage area stenosis rather than on the “worst” percentage diameter stenosis. A related problem is that of the hazy bandlike or membranous stenosis, which may be exceedingly difficult to characterize by standard angiographic views. These unique lesions may simply represent atherosclerosis, or they may be caused by congenital membranous bands. Because of the difficulty in ascertaining the hemodynamic significance of these eccentric and bandlike lesions, measurement of a *fractional flow reserve* (FFR) with a micromanometer-tip guidewire across the region of abnormality during intravenous administration of adenosine may be useful in identifying those patients with hemodynamically significant narrowings (see Chapters 49 and 55).

Superimposition of Branches. Superimposition of major branches of the LCA and RCA can result in failure to detect significant stenoses or total occlusions of these branches. Although this problem most commonly affects the LAD and parallel diagonal branches, side branch overlap also may occur with the ostium of the obtuse marginal branch lesion of the LCx and the origin of the right ventricular branch of the RCA. Moreover, when the LAD is occluded beyond the origin

**TABLE 20-12** Standardized Criteria for Postprocedural Lesion Morphology

FEATURE	DEFINITION
Abrupt closure	Obstruction of contrast flow (TIMI 0 or 1) in a dilated segment with previously documented antegrade flow
Ectasia	A lesion diameter greater than the reference diameter in one or more areas
Luminal irregularities	Arterial contour that has a sawtooth pattern consisting of opacification but not fulfilling the criteria for dissection or intracoronary thrombus
Intimal flap	A discrete filling defect in apparent continuity with the arterial wall
Thrombus dissection*	Discrete, mobile angiographic filling defect with or without contrast staining
A	Small radiolucent area within the lumen of the vessel
B	Linear, nonpersisting extravasation of contrast material
C	Extraluminal, persisting extravasation of contrast material
D	Spiral filling defect
E	Persistent lumen defect with delayed antegrade flow
F	Filling defect accompanied by total coronary occlusion
Dissection, length (mm)	Measure end to end for type B through F dissections
Dissection, staining	Persistence of contrast within the dissection after washout of contrast material from the remaining portion of the vessel
Perforation	
Localized	Extravasation of contrast material confined to the pericardial space immediately surrounding the artery and not associated with clinical tamponade
Nonlocalized	Extravasation of contrast material with a jet not localized to the pericardial space, potentially associated with clinical tamponade
Side branch loss	TIMI 0, 1, or 2 flow in a side branch >1.5 mm in diameter that previously had TIMI 3 flow
Distal embolization	Migration of a filling defect or thrombus to distally occlude the target vessel or one of its branches
Coronary spasm	Transient or permanent narrowing >50% when a <25% stenosis has been previously noted

*National Heart, Lung and Blood Institute classification system for coronary dissection.

of the first septal branch, this branch often becomes quite enlarged in an attempt to provide collateral circulation to the vascular bed of the distal LAD. It is important to obtain sufficient angulation for these views to identify the exact anatomy at the origin of the side branch, such as cranial projections for the LAD artery, caudal projections for the LCx artery, and left lateral projection for the RCA.

Microchannel Recanalization. It is sometimes difficult to differentiate very severe (90%) coronary stenoses (with an antegrade lumen) from total occlusions (with no antegrade lumen) that have been recanalized with microchannels and bridging collaterals. Pathologic studies suggest that approximately one third of totally occluded coronary arteries ultimately recanalize, resulting in the development of multiple tortuous channels that are quite small and close to one another and creating the impression on angiography of a single, slightly irregular channel. Because angiography lacks sufficient resolution to demonstrate this degree of detail in most patients with recanalized total occlusions, wire crossing may not be possible in some cases unless advanced wire techniques are used.

INTRACORONARY IMAGING

Intravascular imaging provides additional information to that obtained with angiography for clinical decision making and insights into the pathology of atherosclerosis and its treatments. Current established imaging modalities include IVUS (see Fig. 20-8), virtual-histology IVUS, optical coherence tomography (OCT), and near-infrared spectroscopy (NIRS).

IVUS and OCT are best used to answer anatomic questions about the structure of arteries and plaque, rather than physiologic or functional consequences of plaque accumulation, which are best addressed by measuring FFR (see Chapters 49 and 54). Virtual-histology IVUS and NIRS provide information on the content of plaque and may help identify more unstable plaque lesions. With

these modalities, changes in lipid content of plaque on serial studies could usefully reflect stability of the plaque.

Imaging Technology Vascular Structure

IVUS and OCT use imaging elements delivered by 2.9F to 3.2F catheters (approximately 1-mm diameter) inserted into an artery. These technologies provide a cross-sectional or tomographic view of vascular structures (Fig. 20-28A, B). IVUS uses ultrasound and OCT uses near-infrared light (approximately 1300 nm wavelength), which are emitted perpendicular to the long axis of the catheter. Two-dimensional images are generated from the echoes of ultrasound or backscattered light using time delays to code distance from the energy source. Both technologies produce a monochrome image using variations in gray scale (IVUS) or sepia (OCT).

IVUS uses two main technologic systems to deliver ultrasound: (1) a mechanical probe with an ultrasound crystal that is rotated at 30 rpm within a catheter and (2) a phased array probe with multiple fixed crystals arranged around the end of a delivery catheter. Ultrasound frequencies are higher for the mechanical probes (30 to 45 MHz) than for the phased array catheters (20 MHz or less). The higher-frequency devices generate an image with slightly better spatial resolution, which refers to the ability to discriminate small objects within the image. High-frequency catheters, however, have less depth penetration and imaging distance (near field), making them unsuitable for use with large-diameter vessels. Resolution for IVUS (at 20 to 45 MHz) axial views (parallel to the radius of the artery) is approximately 100 μ m and for lateral views (perpendicular to the radius) approaches 200 μ m.

Phased array catheters can detect moving blood by a “chromaflo” function (e.g., ChromaFlo IVUS imaging, Volcano Corp., San Diego), which is analogous to power Doppler. This function does not show

FIGURE 20-28 **A**, IVUS image of a normal coronary artery showing the intimal signal (I), adventitia (A), and the borders representing the internal elastic membrane (IEM) and external elastic membrane (EEM) on histologic examination. Ct = catheter. **B**, OCT image of a normal coronary artery showing the same three layers and the media. Asterisk = guidewire artifact. **C**, **D**, IVUS images of a plaque showing the vessel area (VA, yellow outline), the lumen area (LA, red outline), and the plaque area (PA), which is equal to VA – LA.

FIGURE 20-29 **A**, IVUS image of a coronary plaque in standard gray-scale representation. **B**, Virtual-histology IVUS image showing color codes for different tissue types. Upper right, A longitudinal section of the artery with virtual-histology features overlaid on an IVUS pullback image.

direction of flow but detects moving blood cells to help identify the lumen border and dissections. A low-frequency 10-MHz catheter is used for aortic and large-vessel applications (e.g., aortic interventions).

OCT technology systems feature a mechanical catheter and a pull-back device. Because OCT uses light, which has a much shorter wavelength than that of ultrasound, the spatial resolution of OCT is much finer than that afforded by IVUS. With OCT, axial resolution is approximately 10 to 15 μm and lateral resolution is approximately 20 to 40 μm . The improved resolution, however, comes at the expense of a smaller depth of imaging, with tissue penetration of

approximately 2 to 3.5 mm.⁹¹ Because red cells scatter light, the artery is flushed with contrast or saline during imaging with a rapid mechanical pullback of the catheter.

All coronary imaging catheters are delivered through 5F to 6F guiding catheters over an 0.014-inch guidewire using standard interventional techniques. Anticoagulation is required to prevent thrombosis of the equipment. Presence of an imaging catheter can cause arterial spasm, which can increase the risk of catheter-related injury and lead to invalid measurements of artery dimensions. Therefore a bolus dose of 100 to 200 μg of nitroglycerin is delivered into artery through the guide catheter before introduction of the imaging catheter. It is important to maneuver the imaging catheter gently and to avoid excessive force in advancing it into the artery. Older series using larger IVUS catheters reported the risk of dissection and other major complications at less than 1%.

Plaque Content

Validation studies have compared images from virtual-histology IVUS and NIRS technologies with histologic sections of ex vivo arteries with different plaque types.⁹² Virtual-histology IVUS uses spectral analysis of ultrasound backscatter to distinguish among fibrous, calcified, and necrotic core components in the artery intima.⁹² These different tissue types are coded in different colors and overlaid on an IVUS gray-scale image (Fig. 20-29).

NIRS uses a mechanical catheter with dual imaging components and pullback device. The catheter emits a diffuse reflectance near-infrared light (wavelength 0.8 to 2.5 μm). Differences in the absorption pattern of the light identify lipid from other plaque constituents and are represented as a map of the lipid composition of the artery (or chemogram).^{93,94} Two chemogram maps are generated. One shows the lipid content around the artery radius as if the artery were longitudinally sectioned and laid out flat. A smaller chemogram block codes the artery region as lipid only if there is a high probability that the entire slice of the

artery contains lipid⁹⁴ (Fig. 20-30). The other imaging component of the catheter generates an IVUS image, which helps to localize the regions of high lipid content in the artery.

Indications for Intravascular Imaging

Clinical Indications. Intravascular imaging is primarily a tool to distinguish structural abnormalities of arteries and veins. It is most commonly used when there is some doubt of the interpretation of an angiogram.⁹⁵ For example, it can help establish whether a hazy region on angiogram represents a region of calcium, limited dissection,

FIGURE 20-30 Representative NIRS and corresponding IVUS images. A, B, and C are adjacent regions in a coronary artery on gray-scale ultrasound images (top panel) and in longitudinal section (middle panel). Region A has a signal-poor region on the gray-scale IVUS image (arrows in top panel). The corresponding NIRS chemogram (bottom panel) shows a circumferential lipid core plaque in region A as yellow in the chemogram and yellow and tan blocks in the block chemogram (BC). Region B exhibits homogeneous plaque on the gray-scale ultrasound image (top panel), and the chemogram shows no lipid content. Region C shows a calcified plaque on IVUS (arrow in top panel), with little lipid in the chemogram. (From Pu J, Mintz GS, Brilakis ES, et al: *In vivo* characterization of coronary plaques: Novel findings from comparing greyscale and virtual histology intravascular ultrasound and near-infrared spectroscopy. *Eur Heart J* 33:372, 2012).

intramural hematoma, or atheroma causing stenosis. Imaging also can assist PCI. For example, showing inadequately dilated stents or edge dissections adjacent to a stent (Fig. 20-31). Imaging also can help measure the reference size of an artery to avoid using balloons or stents that are too large and likely to cause edge dissections or other complications from PCI. The reference size usually is the lumen area (see Fig. 20-28D) or diameter from a more normal segment proximal and distal to a stenosis.

Although in the past, imaging was used to help ascertain the functional significance of a stenosis (as likely to cause angina), this indication has largely been superseded by measurement of FFR.⁹⁶ However, correlation studies with FFR, nuclear stress tests, and deferred PCI suggest that a lumen cross-sectional area in the major coronary arteries of less than 4.0 mm² is likely to represent a functionally significant stenosis.⁹⁷ The significance of LMCA stenosis is less clear, with IVUS criteria for significant LMCA disease ranging from less than 4.5 to 7.5 mm² (see Fig. 20-8).⁹⁷

Research Indications. Intravascular imaging can provide insights into the mechanisms of failure or success of PCI and medical therapies directed against atherosclerosis.⁹⁸⁻¹⁰⁰ Research applications use more detailed techniques to quantify the changes in plaque and vessel area between groups or over time within individuals (see Fig. 20-28C, D). Because differences in these measurements usually are quite small, such quantification requires offline analysis of IVUS images by trained personnel who are blinded to the intervention or group allocation, and have acceptable between-person and within-person reproducibility in measuring images. Comparisons of images over time require reproduction of the original conditions of baseline study by matching the catheter placement to landmarks on the angiogram, and starting the IVUS analysis at a recognizable side-branch vessel on the IVUS run (the fiduciary branch).

Examples of the application of intravascular imaging in research are assessing the contribution of vessel remodeling and neointimal growth to restenosis and in-stent restenosis after PCI and identifying differences in plaque progression with lipid-lowering therapies.^{99,100}

Virtual-histology IVUS and NIRS offer the ability to assess changes in the composition of plaque with interventions. For example, lipid-lowering interventions that decrease the size of the necrotic core on virtual histology, or the size of lipid plaques on NIRS, potentially provide mechanisms for lipid-lowering therapies, or possibly identify novel therapies to prevent clinical events such as acute MI that require further evaluation in larger clinical trials.

Evaluating an Image

Normal Arteries

Normal medium-sized muscular arteries, such as the coronary artery, have three distinct layers. From the artery lumen outward, these are the intima, media, and adventitia. Because ultrasound and light are reflected from adjacent structures with different transmission qualities, an intimal signal often can be identified even in “normal” arteries (see Fig. 20-28A, B). Very thin intimal signals more often overestimate the true intimal thickness, particularly with IVUS. The transition between intima and media corresponds histologically to the internal elastic lamina. The media, which primarily consists of vascular smooth muscle, also is distinguishable from the adventitia by a signal-poor region, and the transition corresponds to the external elastic lamina. These structures are more easily identifiable by OCT than by IVUS (see Fig. 20-28B). Because the guidewire lies adjacent to the imaging portion of mechanical catheters, it appears as an artifact with a shadow in these images. The wire passes through the center of a phased array IVUS catheter and is not seen on these images.

Plaque Characteristics

IVUS and OCT are good at identifying calcium in plaque, and less so at identifying fibrous and lipid tissue. In IVUS images, calcium appears as a bright echogenic signal with a corresponding shadow and the far side of the calcium (Fig. 20-32A). Bright signals without a shadow can be due to dense fibrous tissue or the ultrasound gain set at a high level. In OCT images, calcium appears as an area of reduced signal intensity with well-demarcated borders (Fig. 20-32B).

Fibrous tissue appears as an area of homogeneous signal intensity beneath the media (i.e., in the intima) on both IVUS and OCT images (Fig. 20-32C; see also Fig. 20-32B). IVUS does not identify lipid well,

FIGURE 20-31 **A**, IVUS image showing an inadequately dilated stent with stent struts in the lumen (white arrows) and not against the wall (yellow arrow). **B**, OCT image showing malapposed stent struts in the lumen (white arrows) and not against the wall. Asterisk = guidewire artifact. **C**, IVUS image showing a linear intimal dissection (white arrow). **D**, OCT image showing a dissection flap (arrow) adjacent to intimal calcium (Ca) after balloon dilation.

but echolucent areas beneath plaques may represent lipid pools or necrotic lipid cores of plaques. Similarly, lipid collections are not easily discerned by OCT. They usually are identified as signal-poor regions with poorly defined edges (see Fig. 20-32B). In some cases, OCT can discriminate a thin fibrous cap over a lipid plaque, but recent guidelines suggest that more studies correlating OCT with histologic findings are needed to refine the criteria for these plaques.⁹¹ Other features such as cholesterol crystals and macrophage accumulation are documented, but the evidence supporting the sensitivity of these findings is not as good as for identification of the main tissue types (calcium, fibrous, and lipid).⁹¹

Thrombus and Ruptured Plaques

Acute coronary syndromes characteristically are caused by disrupted plaques associated with lumen thrombus (see Chapters 41 and 51). Overlying thrombus is the key indicator of a plaque rupture or erosion. It may not be present in all cases or may obscure the underlying plaque if large (Fig. 20-32D). Thrombus is poorly visualized by IVUS but appears as an amorphous irregular object, often with a signal-poor region beyond its surface, on OCT images. Plaque rupture is suggested by the presence of an ulcerated lesion within the plaque, often with residual elements of the ruptured cap (Fig. 20-32E, F). These features are best seen on OCT images, because of proximity to the lumen and better spatial resolution (see Fig. 20-32F).

Percutaneous Interventions

Two key uses of intravascular imaging during PCI (see Chapter 55) are to assess the reference size of the artery and to identify

the edges of stents are more adequately expanded, because these usually are on either side of the tightest region of the stenosis and located in a more compliant part of the artery. Presence of heavy calcification can impair stent expansion and necessitate a higher balloon pressure or larger balloon inflation.

FUTURE PERSPECTIVES

Novel technologies and applications of intravascular imaging have the potential to advance current understanding of cardiovascular disease processes and to aid PCI. Molecular imaging offers the potential to identify plaques with high levels of inflammatory cell activity, which are prone to disruption. For example, near-infrared fluorescent dyes tagged to moieties specific to molecules expressed by activated endothelial cells (e.g., vascular cell adhesion molecule-1) may potentially be used with intravascular catheters to identify regions of endothelial cell activation and increased vascular inflammation.¹⁰¹ Other probes detecting metalloproteinase activity in plaques that is activated by near-infrared fluorescence may potentially identify regions in plaque with high macrophage activity.

Higher-frequency IVUS (e.g., 60 MHz) offers the potential for improving the resolution of IVUS, with better tissue penetration than with OCT. With higher-frequency IVUS catheters, however, blood typically exhibits higher signal intensity, making it difficult to recognize the lumen border. Forward-looking IVUS attempts to look ahead of the catheter and could potentially help guide interventional equipment through total occlusions.

inadequate or adverse results from interventions. Although it is tempting to use the external elastic lamina at the site of a stenosis as the reference size of the artery, this does not take into account arterial remodeling (see Chapter 41). The artery can remodel outward to accommodate plaque in an artery or remodel inward, contributing to lumen stenosis. Early studies found a higher rate of coronary dissection when the external elastic lamina was used as the reference size for balloons and stents. Fewer adverse events occurred when the lumen diameters of more normal sites proximal and distal to a stenosis were used as the reference size.

Intravascular imaging is particularly useful in identifying features associated with poorer clinical outcomes. Such features include under-expansion of a stent and grossly unapposed stent struts (see Fig. 20-31A, B). These defects can increase the risk of stent thrombosis and indicate the need for dilation with larger balloons or at higher pressures. Balloon inflation may cause dissections and dilation of the artery (see Fig. 20-31C, D). Large dissections and smaller “edge dissections” at the ends of stents can increase the risk of thrombosis or abrupt closure. Dissections appear as crescent-shaped structures or fronds projecting into the lumen and often are mobile (see Fig. 20-31C, D; see also Fig 20-32B).

Underdilated stents are identified by comparison of the stented segment to reference segments or the edges of the stent by IVUS or OCT. Typically

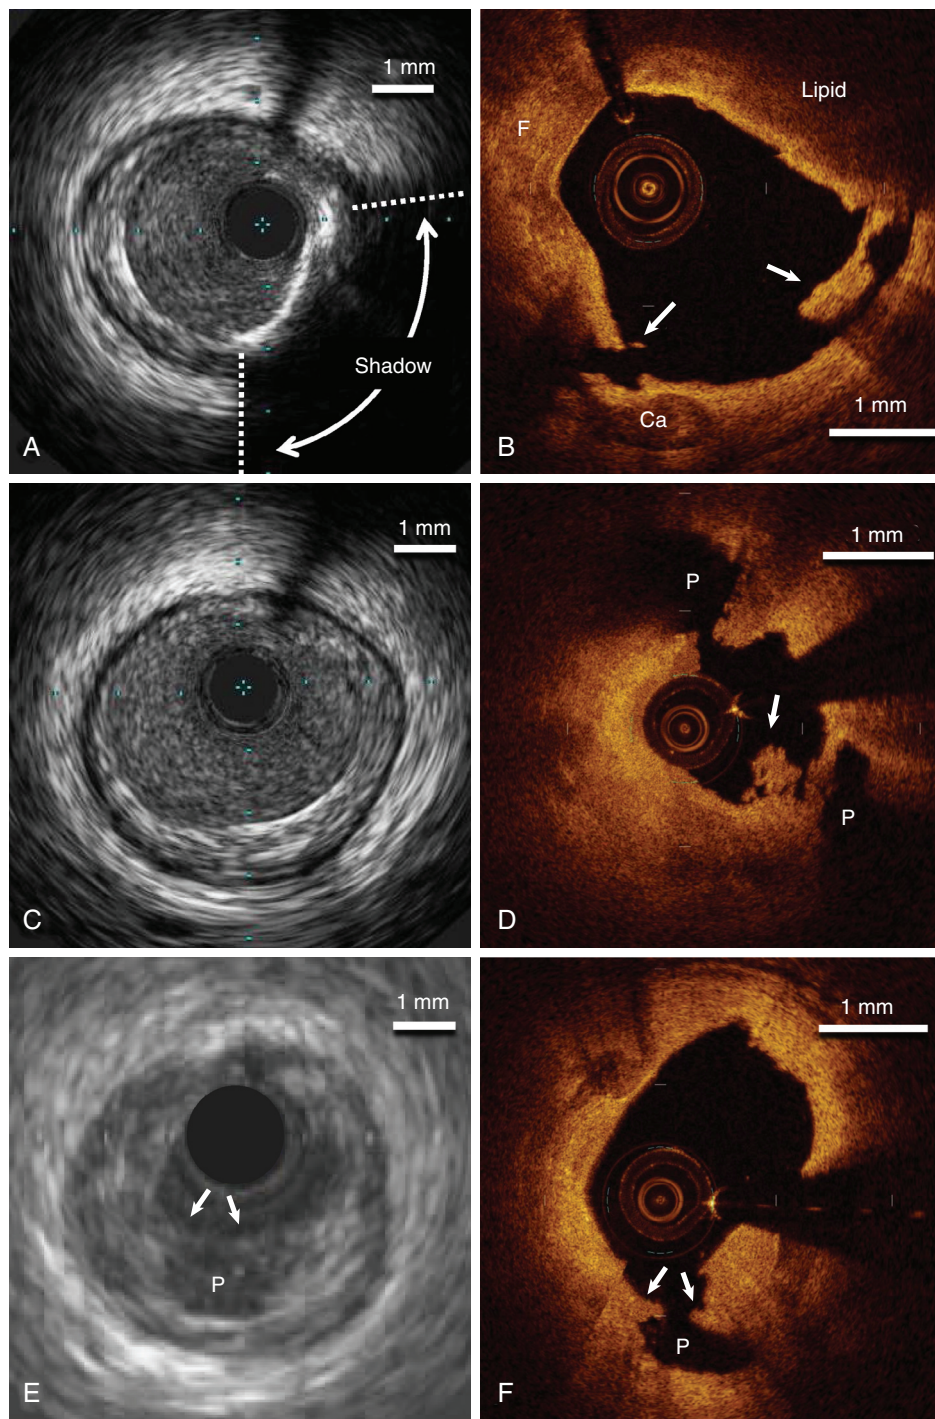

FIGURE 20-32 **A**, IVUS image showing bright echogenic signal from 3 to 6 o'clock with shadow characteristic of a calcified plaque. **B**, OCT image of a plaque showing fibrous tissue with a homogeneous signal (F), lipid plaque with a signal-poor region with ill-defined borders (Lipid), and a signal-poor region with well-defined borders typical of calcium (Ca). APPROPRIATE USE CRITERIA

Multimodality Imaging in Stable Ischemic Heart Disease and Heart Failure

James E. Udelson, Vasken Dilsizian, and Robert O. Bonow

Beginning in 2005, the American College of Cardiology along with other professional societies have published Appropriate Use Criteria

(AUC), a set of recommendations for the use of diagnostic and therapeutic procedures keyed to clinical situations. With respect to diagnostic imaging, since publication of the initial document on single photon emission computed tomography (SPECT) imaging in 2005, each AUC document considered an individual imaging test or procedure (such as SPECT or echocardiography) across numerous clinical indications. The AUC recommendations are meant to inform clinical decision making for the optimal use of cardiac imaging.

Two newly published documents provide recommendations for the appropriate use of imaging in clinical syndromes, rather than focusing on one specific imaging modality alone. The recommendations apply in all patients with stable ischemic heart disease, that is, those with suspected or known CAD (**Table 20G-1**)¹ and patients with heart failure (**Table 20G-2**)² and present criteria for the use of numerous

TABLE 20G-1 Multimodality Appropriate Use Criteria for the Detection and Risk Assessment of Stable Ischemic Heart Disease

INDICATION		EXERCISE ECG	STRESS RNI	STRESS ECHO	STRESS CMR	CALCIUM SCORING	CCTA	INVASIVE CORONARY ANGIOGRAPHY
Section 1. Detection of CAD/Risk Assessment								
1.1 Symptomatic								
1.	Low pretest probability of CAD ECG interpretable AND able to exercise	A	R	M	R	R	R	R
2.	Low pretest probability of CAD ECG uninterpretable OR unable to exercise	—	A	A	M	R	M	R
3.	Intermediate pretest probability of CAD ECG interpretable AND able to exercise	A	A	A	M	R	M	R
4.	Intermediate pretest probability of CAD ECG uninterpretable OR unable to exercise	—	A	A	A	R	A	M
5.	High pretest probability of CAD ECG interpretable AND able to exercise	M	A	A	A	R	M	A
6.	High pretest probability of CAD ECG uninterpretable OR unable to exercise	—	A	A	A	R	M	A
1.2. Asymptomatic (Without Symptoms or Ischemic Equivalent)								
7.	Low global CHD risk Regardless of ECG interpretability and ability to exercise	R	R	R	R	R	R	R
8.	Intermediate global CHD risk ECG interpretable AND able to exercise	M	R	R	R	M	R	R
9.	Intermediate global CHD risk ECG uninterpretable OR unable to exercise	—	M	M	R	M	R	R
10.	High global CAD risk ECG interpretable AND able to exercise	A	M	M	M	M	M	R
11.	High global CAD risk ECG uninterpretable OR unable to exercise	—	M	M	M	M	M	R
1.3. Other Cardiovascular Conditions								
Newly Diagnosed Heart Failure (Resting LV Function Previously Assessed but No Previous CAD Evaluation)								
12.	Newly diagnosed systolic heart failure	M	A	A	A	R	A	A
13.	Newly diagnosed diastolic heart failure	M	A	A	A	R	M	M
Evaluation of Arrhythmias Without Ischemic Equivalent (No Prior Cardiac Evaluation)								
14.	Sustained VT	A	A	A	A	R	M	A
15.	Ventricular fibrillation	M	A	A	A	R	M	A
16.	Exercise-induced VT or nonsustained VT	A	A	A	A	R	M	A

TABLE 20G-1 Multimodality Appropriate Use Criteria for the Detection and Risk Assessment of Stable Ischemic Heart Disease—cont'd

INDICATION		EXERCISE ECG	STRESS RNI	STRESS ECHO	STRESS CMR	CALCIUM SCORING	CCTA	INVASIVE CORONARY ANGIOGRAPHY
17.	Frequent PVCs	A	A	A	M	R	M	M
18.	Infrequent PVCs	M	M	M	R	R	R	R
19.	New-onset atrial fibrillation	M	M	M	R	R	R	R
20.	Before initiation of antiarrhythmia therapy in patients with high global CAD risk	A	A	A	A	R	M	R
Syncope Without Ischemic Equivalent								
21.	Low global CAD risk	M	M	M	R	R	R	R
22.	Intermediate or high global CAD risk	A	A	A	M	R	M	R
Section 2. Previous Testing or Procedure								
Section 2.1. Previous Testing Without Intervening Revascularization (with intervening revascularization since most recent test, refer to Section 2.2)								
2.0. Sequential Testing (≤ 90 Days): Abnormal Previous Test/Study								
23.	Abnormal at-rest ECG findings (potentially ischemic in nature such as LBBB, T wave inversions) Low global CAD risk	—	A	A	M	R	M	R
24.	Abnormal at-rest ECG findings (potentially ischemic in nature such as LBBB, T wave inversions) Intermediate to high global CAD risk	—	A	A	A	R	M	M
25.	Abnormal previous exercise ECG test	—	A	A	A	R	A	A
26.	Abnormal previous stress imaging study (assumes not repeat of same type of stress imaging)	R	M	M	M	R	A	A
27.	Obstructive CAD on previous CCTA study	M	A	A	A	—	—	A
28.	Obstructive CAD on previous invasive coronary angiography	M	A	A	A	R	R	—
29.	Abnormal previous CCT calcium (Agatston score >100)	A	A	A	M	—	M	R
2.1. Sequential or Follow-Up Testing (≤ 90 Days): Uncertain Prior Results								
Equivocal, Borderline, or Discordant Previous Noninvasive Evaluation When Obstructive CAD Remains a Concern								
30.	Previous exercise ECG test	—	A	A	A	R	A	M
31.	Previous stress imaging study (assumes not repeat of same type of stress imaging)	R	M	M	M	R	A	A
32.	Previous CCTA	M	A	A	A	—	—	A
Prior Coronary Angiography (Invasive or Noninvasive)								
33.	Coronary stenosis or anatomic abnormality of unclear significance found on cardiac CCTA	M	A	A	A	—	—	A
34.	Coronary stenosis or anatomic abnormality of unclear significance on previous coronary angiography	M	A	A	A	R	R	—
2.2. Follow-Up Testing (>90 Days): Asymptomatic or Stable Symptoms								
Abnormal Previous Exercise ECG Test, Asymptomatic or Stable Symptoms								
35.	Last test <2 years ago	R	R	R	R	R	R	R
36.	Last test ≥ 2 years ago	M	M	M	R	R	R	R
Abnormal Previous Stress Imaging Study, Asymptomatic or Stable Symptoms

testing modalities within each of those clinical syndromes, including exercise electrocardiography and all widely used imaging modalities such as SPECT perfusion imaging, echocardiography, coronary computed tomography angiography (CCTA) and calcium imaging, and cardiac magnetic resonance imaging (CMR). Testing is rated on the basis of the published literature, as well as expert opinion, in a well-defined process. Tests are rated using the current nomenclature as “appropriate,” “may be appropriate,” or “rarely appropriate.”³

Although these documents in large part reflect the criteria in the previously published documents for each of the individual modalities, additional recommendations have been developed based on more recent published data. This is particularly true for newer modalities such as CCTA and CMR, for which data continue to evolve. Thus the recommendations in these newer documents supersede those in previous AUC documents on the individual modalities (see Guidelines and Appropriate Use Criteria sections for [Chapters 14, 16, 17, 18, and 19](#)). Moreover, a strength of these multimodality documents is that the writing panel had as one of its goals to “... identify any and all tests that are considered reasonable for a given clinical indication.”¹ The panel did not attempt to define which test might be “best” for each indication but rather to identify the range of testing that could be appropriate (or not) for a given clinical indication within the specific clinical syndrome. It is acknowledged that local expertise and

quality of testing is an additional critical factor in determining test selection.

The AUC documents have been important in identifying, for individual practice imaging laboratories and hospital systems, that approximately 15% of tests that are ordered appear to fall into the category “rarely appropriate”; they also provide clinicians with a guide to optimize case selection for testing, as well as test selection. The multimodality imaging AUC documents comprehensively compile the recommendations for all imaging modalities and are important guides to clinical practice.

MICROANATOMY OF CONTRACTILE CELLS AND PROTEINS

Ultrastructure of Contractile Cells

The major function of cardiac muscle cells (*cardiomyocytes* or *myocytes*) is to execute the cardiac contraction-relaxation cycle. The contractile proteins of the heart lie within these myocytes, which constitute approximately 75% of the total volume of the myocardium, although only approximately one third of the number of all the cells.¹⁻⁴ Approximately half of each ventricular cell is occupied by the myofibrils of the myofibers (**Fig. 21-1**) and approximately one quarter to one third by mitochondria (**Table 21-1**). A *myofiber* is a group of myocytes (**Fig. 21-1**) held together by surrounding collagen connective tissue, the latter being a major component of the extracellular matrix. Further strands of collagen connect myofibers to each other.

The individual contractile myocytes account for more than half the heart's weight. Ventricular myocytes are roughly brick shaped, typically $150 \times 20 \times 12 \mu m$ (**Table 21-1**), and are connected at the long ends (**Fig. 21-2**). Those in the atrium are smaller and more spindle shaped ($<10 \mu m$ in diameter and $<100 \mu m$ in length). When examined under a light microscope, atrial and ventricular myocytes have cross striations and are often branched. Each myocyte is bounded by a complex cell membrane, the *sarcolemma* (*sarco* = flesh; *lemma* = thin husk), and is filled with rodlike bundles of *myofibrils* (see **Fig. 21-1**), which are the contractile elements. The myocyte sarcolemma

invaginates to form an extensive tubular network (the *T tubules*) that extends the extracellular space into the interior of the cell (see **Figs. 21-1** and **21-2**). Ventricular myocytes are typically binucleate, and these nuclei contain most of the cell's genetic information. Some myocytes have one or several nuclei. Rows of mitochondria are located between the myofibrils and also immediately beneath the sarcolemma. Mitochondria function mainly to generate the energy, in the form of adenosine triphosphate (ATP), that is needed to maintain the heart's contractile function and the associated ion gradients. The *sarcoplasmic reticulum* (SR) is a specialized form of endoplasmic reticulum that is critical for calcium (Ca^{2+}) cycling, which is the on-off switch for contraction (see **Fig. 21-1**). When the wave of electrical excitation reaches the T tubules, voltage-gated Ca^{2+} channels open to provide relatively small entry of Ca^{2+} , which triggers additional release of Ca^{2+} from the SR via closely apposed release channels. This is the Ca^{2+} that initiates myocardial contraction. Ca^{2+} sequestration by the SR causes relaxation (diastole).

Anatomically, the SR is a lipid membrane-bounded, fine interconnected network spreading throughout the myocytes. The *Ca^{2+} release channels* (or *ryanodine receptors* [RyRs]) are concentrated at the part of the SR that is in very close apposition to the T tubular Ca^{2+} channel. These are called *terminal cisternae* (boxes or baskets, Latin) or the *junctional SR* (jSR). The second part of the SR, the *longitudinal, free, or network SR*, consists of ramifying tubules that surround the myofibrils (see **Fig. 21-1**) that take Ca^{2+} back up into the SR and thus drive relaxation. Such uptake is achieved by the ATP-requiring Ca^{2+}

FIGURE 21-1 The crux of the contractile process lies in the changing $[Ca^{2+}]$ in the myocardial cytosol. Ca^{2+} ions are shown entering via the Ca^{2+} channel, which opens in response to the wave of depolarization that travels along the sarcolemma. These Ca^{2+} ions “trigger” the release of more Ca^{2+} from the SR and thereby initiate a contraction-relaxation cycle. Eventually, the small amount of Ca^{2+} that has entered the cell will leave predominantly by an Na^{+}/Ca^{2+} exchanger, with a lesser role for the sarcolemmal Ca^{2+} pump. The varying actin-myosin overlap is shown for systole, when Ca^{2+} arrives, and for diastole, when Ca^{2+} leaves. The myosin heads, attached to the thick filaments, interact with the thin actin filaments, as shown in Figure 21-6. For role of titin, see Figure 21-5. The **upper panel** shows the difference between the myocardial cell or myocyte and the myofiber, which is composed of many myocytes. (**Upper panel**, Reproduced from Braunwald E, Ross J, Sonnenblick EH: *Mechanisms of Contraction of the Normal and Failing Heart*. 2nd ed. Boston, Little, Brown, 1976; **other panels**, reprinted from Opie LH: *Heart Physiology*, from *Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004.)

pump known as *SERCA* (sarcoendoplasmic reticulum Ca^{2+} -adenosine triphosphatase [ATPase]). The Ca^{2+} taken up into the SR is then stored at high concentration, in part bound to storage proteins, including *calsequestrin*, before being released again in response to the next wave of depolarization. *Cytoplasm* or *sarcoplasm* refers to the intracellular fluid and proteins therein, but excludes the contents of organelles such as the mitochondria, nucleus, and SR. The cytoplasm is crowded with myofilaments, but this is the fluid within which

the concentration of Ca^{2+} rises and falls to cause cardiac contraction and relaxation.

Subcellular Microarchitecture

The molecular signal systems that convey messages from surface receptors to intracellular organelles may be directed to specific sites by molecules that “anchor” components of the signaling cascades to specific loci, such as around beta-adrenergic receptors and Ca^{2+} channels at the T tubule–SR junction and *caveolae* (small flask-shaped sarcolemmal invaginations). *Scaffolding proteins* such as caveolin or the RyR bring interacting molecules closely together at these locations. These complexes can release components that translocate and signal elsewhere in the cell, such as the nucleus, where it can signal for myocyte growth. Another type of subcellular shuttling is involved in getting the ATP produced in mitochondria to sites where it is used (e.g., myofilaments), which is facilitated by the location of creatine kinase, an enzyme that converts creatine phosphate to ATP.

Mitochondrial Morphology and Function

The typical ventricular myocyte has approximately 8000 mitochondria, each of which is ovate with a long axis measuring 1 to 2 μm and short axis of 300 to 500 nm. There are two membranes, the outer and inner mitochondrial membranes (OMM and IMM; Fig. 21-3). The IMM is “crumpled” such that it forms a large surface area within a small volume, and it contains the cytochrome complexes that make up the respiratory chain, including F_0F_1 ATP synthase. The space within the IMM, the mitochondrial matrix, contains enzymes of the tricarboxylic acid (TCA) cycle and other key metabolic components. These components provide reducing equivalent protons that are pumped out of the matrix by the cytochromes, and it is this proton pumping that creates the very negative matrix potential with respect to cytosol ($\Psi_m = -180$ mV). Such a negative Ψ_m creates a strong electrochemical gradient for protons, which as they flow down this energy gradient on F_0F_1 ATP synthase, are responsible for making

ATP. The ATP still needs to get out of the mitochondria, and an adenine nucleotide transporter exchanges mitochondrial ATP for cytosolic adenosine diphosphate (ADP). This system is exquisitely regulated to maintain cytosolic [ATP] and [ADP] constant during the dramatic changes in cardiac workload.⁵ The multiple control mechanisms involved in this process are not fully understood, but one is quite relevant to the excitation-contraction coupling process. Increased cardiac work in a physiologic setting is usually driven by

TABLE 21-1 Characteristics of Cardiac Cells, Organelles, and Contractile Proteins

MICROANATOMY OF HEART CELLS			
	Ventricular Myocyte	Atrial Myocyte	Purkinje Cells
Shape	Long and narrow	Elliptical	Long and broad
Length (μm)	75-170	20-100	150-200
Diameter (μm)	15-30	5-6	35-40
Volume (μm ³)	15,000-100,000	400-1500	135,000-250,000
T tubules	Plentiful	Rare or none	Absent
Intercalated disc	Prominent end-to-end transmission	Side-to-side as well as end-to-end transmission	Very prominent abundant gap junctions. Fast; end-to-end transmission
General appearance	Mitochondria and sarcomeres very abundant. Rectangular branching bundles with little interstitial collagen	Bundles of atrial tissue separated by wide areas of collagen	Fewer sarcomeres, paler

COMPOSITION AND FUNCTION OF VENTRICULAR CELL		
Organelle	Percentage of cell volume	Function
Myofibril	≈50-60	Interaction of thick and thin filaments during contraction cycle
Mitochondria	16 in neonate 33 in adult rat 23 in adult man	Provide ATP chiefly for contraction
T-system	≈1	Transmission of electrical signal from sarcolemma to cell interior
SR	10 in neonate 2 in adult	Takes up and releases Ca ²⁺ during contraction cycle
SR terminal cisternae	0.33 in adult	Site of calcium storage and release
Rest of network of SR	Rest of volume	Site of calcium uptake en route to cisternae
Sarcolemma	Very low	Control of ionic gradients, channels for ions (action potential), maintenance of cell integrity, receptors for drugs and hormones
Nucleus	≈3	Transcription
Lysosomes	Very low	Intracellular digestion and proteolysis
Sarcoplasm (= cytoplasm) (includes myofibril but not mitochondria or SR)	60-65	Cytosolic volume within which [Ca _i] rises and falls

FIGURE 21-2 The sarcomere is the distance between the two Z-lines. Note the presence of numerous mitochondria (mit) sandwiched between the myofibrils and the presence of T tubules (T), which penetrate into the muscle at the level of the Z-lines. This two-dimensional picture should not disguise the fact that the Z-line is really a "Z-disc," as is the M-line (M), also shown in Figure 21-1. A = band of actin-myosin overlap; g = glycogen granules; H = central clear zone containing only myosin filament bodies and the M-line; I = band of actin filaments, titin, and Z-line (rat papillary muscle, 32,000×). (Courtesy Dr. J. Moravec, Dijon, France.)

Mitochondrial Ca and Na Transport: Connection to Metabolism

FIGURE 21-3 Mitochondrial Ca²⁺ regulation. The intramitochondrial matrix is very negative with respect to the cytosol (−180 mV). Ca²⁺ enters mitochondria via the Ca²⁺ uniporter and is extruded by Na/Ca exchange. Na⁺ is extruded via Na/H exchange. Protons (H⁺) are pumped out of mitochondria by the cytochrome (Cyto) systems, thereby allowing H⁺ to enter via F₀-F₁ ATP synthase (ATP). When mitochondrial [Ca] is increased, it activates mitochondrial dehydrogenases, which increase NADH levels and provide additional reducing equivalent protons to the electron transport chain. (Modified from Bers DM: *Excitation-Contraction Coupling and Cardiac Contractile Force*. Dordrecht, Netherlands, Kluwer Academic, 2001.)

higher-amplitude and/or more-frequent Ca^{2+} transients. This elevation in average $[\text{Ca}^{2+}]_i$ also increases mitochondrial matrix $[\text{Ca}]$ ($[\text{Ca}^{2+}]_m$), which activates key dehydrogenases in the TCA cycle and also pyruvate dehydrogenase to restore levels of nicotinamide adenine dinucleotide, reduced form (NADH), and thereby increase cytochrome activity and hence restore or maintain $[\text{ATP}]$ toward normal levels.

The above raises the issue of how mitochondria regulate $[\text{Ca}^{2+}]_m$ because there is also a huge electrochemical gradient favoring entry of Ca^{2+} into mitochondria.³ Indeed, $[\text{Ca}^{2+}]_m$ is normally not much different from $[\text{Ca}^{2+}]_i$ and is kept at that level by a mitochondrial Na/Ca exchanger (NCXL), which uses the also steep Na^+ electrochemical gradient to pump Ca^{2+} out of the mitochondria. However, this would of course load the mitochondria with Na^+ , so Na^+ must also be extruded from the mitochondria. This is accomplished by an Na/H exchanger in the IMM, but a consequence is that this influx of H^+ costs energy. That is, these protons could have entered the mitochondria via the $\text{F}_0\text{-F}_1$ ATP synthase making ATP, but instead they were used to extrude Na^+ and Ca^{2+} . So in a sense the mitochondrion can make ATP or extrude Ca^{2+} . This becomes important when myocytes (or other cells) suffer from Ca^{2+} overload. In the short term, mitochondria can take up large amounts of Ca^{2+} to protect the cell from short-term Ca^{2+} overload, but chronic high $[\text{Ca}^{2+}]_i$ has dire consequences. First, this Ca^{2+} uptake can diminish Ψ_m and occurs at the expense of ATP production (as noted), thus hampering energetic recovery from such stress. Second, elevated $[\text{Ca}^{2+}]_i$ and $[\text{Ca}^{2+}]_m$ can facilitate opening of the mitochondrial permeability transition pore, which allows the matrix contents to be released to the cytosol, wipes out Ψ_m , and can be the death knell for individual mitochondria, as well as the cells that rely on their function.

Thus mitochondria can rapidly change into death-promoting organelles as just mentioned and also by producing excessive reactive oxygen species (ROS), which can promote necrotic cell death via the mitochondrial permeability transition pore and release of proapoptotic proteins⁶ (see Chapter 22). Mitochondria can also induce mitochondrial autophagy, or *mitophagy*, which selectively clears damaged mitochondria and favors adaptation to stress by removing damaged mitochondria. Increased oxidative stress and apoptotic proteases can inactivate mitophagy and thereby cause cell death.⁷

Contractile Proteins

The two chief contractile proteins are the motor protein myosin on the thick filament and actin on the thin filament (see Fig. 21-1). Ca^{2+} initiates the contraction cycle by binding to the thin filament regulatory protein troponin C to relieve the inhibition otherwise exerted by this troponin complex (Fig. 21-4). The thin actin filaments are connected to the Z-lines (Z, abbreviation for German *Zuckung*, or contraction; see Figs. 21-1 and 21-2) at either end of the sarcomere, which is

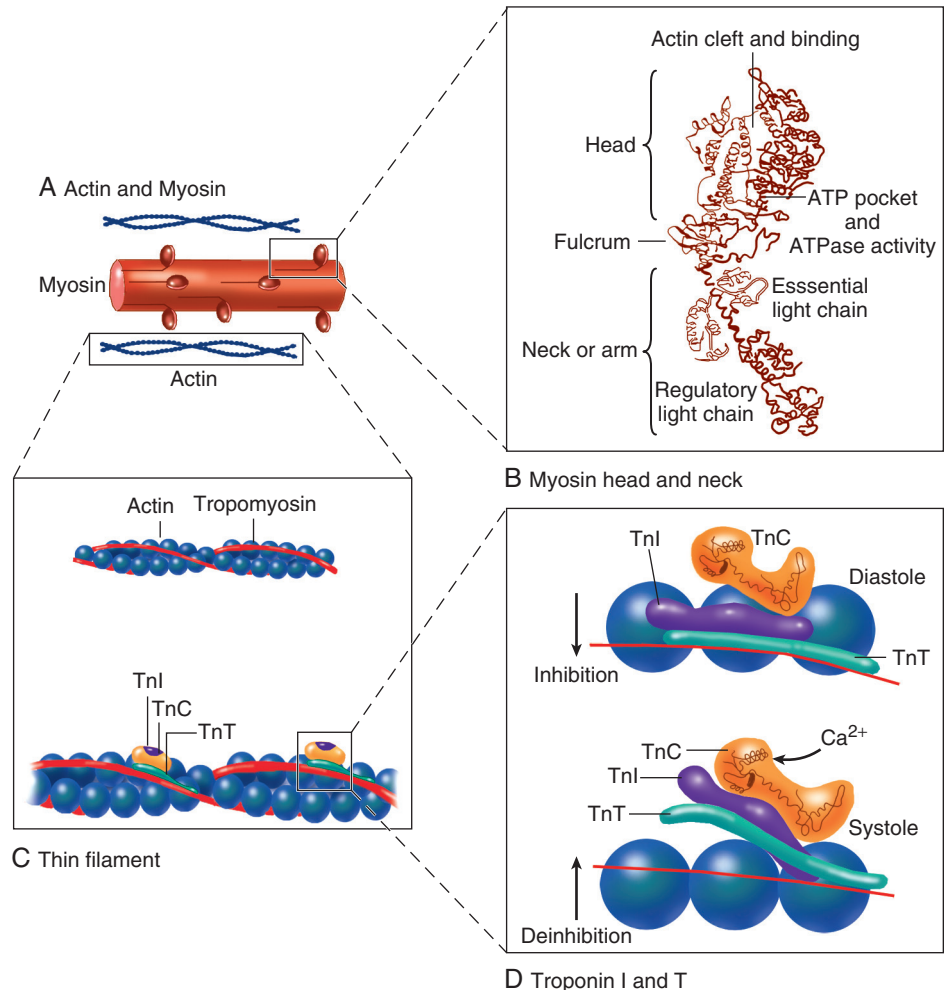

FIGURE 21-4 Major molecules of the contractile system. The thin actin filament (**A**) interacts with the myosin head (**B**) when Ca^{2+} ions arrive at troponin C (TnC) (**C**). A complex interaction between TnC and the other troponins moves tropomyosin to “uncover” an actin site to which a myosin head can attach. The molecular aspects are as follows. **A**, The thin actin filament contains TnC and its Ca^{2+} binding sites. When TnC is not activated by Ca^{2+} , troponin I (TnI) inhibits the actin-myosin interaction. Troponin T (TnT) is an elongated protein that interacts with all the other components of the thin filament, thereby participating in the activation cycle (**D**). **B**, The molecular structure of the myosin head, based on Rayment and colleagues,⁸ is composed of heavy and light chains. The heavy head chain in turn has two major domains: one of 70 kDa (i.e., 70,000 molecular weight) that interacts with actin at the actin cleft and has an ATP binding pocket. The “neck” domain of 20 kDa, also called the “lever,” is an elongated alpha helix that extends and bends and has two light chains surrounding it as a collar. The essential light chain is part of the structure. The other regulatory light chain may respond to phosphorylation to influence the extent of the actin-myosin interaction. **C**, TnC with sites in the regulatory domain for activation by calcium and for interaction with TnI. **D**, Binding of calcium to TnC induces a conformational change in TnC, which elongates (compare systole with diastole). TnI closes up to TnC, and the normal inhibition of TnI on actin-tropomyosin is lessened; however, the interaction between TnC and TnT is strengthened. These changes allow repositioning of tropomyosin in relation to actin, with lessening of its normal inhibitory effects, as shown in the bottom panel. Now the contractile cycle can start. (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L. H. Opie, © 2004. **D**, Modified from Solaro RJ, Van Eyk J: Altered interactions among thin filament proteins modulate cardiac function. *J Mol Cell Cardiol* 28:217, 1999.)

the functional contractile unit that is repeated through the filaments. The sarcomere is limited on either side by a Z-line, which with the thin filaments creates a sort of cage around the thick myosin filament that extends from the center of the sarcomere outward toward, but not reaching the Z-line. During contraction, the myosin heads grab onto actin and pull the actin filaments toward the center of the sarcomere. The thin and thick filaments can thus slide over each other to shorten the sarcomere and cell length (without the individual actin or myosin molecules actually shortening).

The interaction of the myosin heads with actin filaments when sufficient Ca^{2+} arrives from the SR (see Fig. 21-1) is called *cross-bridge cycling*. As the actin filaments move inward toward the center of the sarcomere, they draw the Z-lines closer together so that the sarcomere shortens. The energy for this shortening is provided by the breakdown of ATP, made chiefly in the mitochondria.

Titin and Length Sensing

Titin is a giant molecule, the largest protein yet described. It is an extraordinarily long, flexible, and slender myofibrillar protein (Fig. 21-5). Titin extends from the Z-line but stops just short of the M-line connecting the thick filament to the Z-line (see Fig. 21-1) and provides elasticity. Titin has two distinct segments: an inextensible anchoring segment and an extensible elastic segment that stretches as sarcomere length increases. So the titin molecule can stretch between 0.6 and 1.2 μm in length and has multiple functions. First, it tethers the myosin molecule to the Z-line, thereby stabilizing the contractile proteins. Second, as it stretches and relaxes, its elasticity contributes to the stress-strain relationship of cardiac and skeletal muscle. At short sarcomere lengths, the elastic domain is folded on itself to generate restoring force (Fig. 21-5). These changes in titin help explain the *series elastic element* that was inferred from mechanics studies as elasticity in series with the myosin filaments. Third, the increased diastolic stretch of titin as the length of the sarcomere in

cardiac muscle is increased causes the enfolded part of the titin molecule to straighten. This stretched molecular spring then contracts more vigorously in systole.⁴ Fourth, titin may transduce mechanical stretch into growth signals. With sustained diastolic stretch, as in volume overload, the elastic segment of titin is under constant strain and transmits this mechanical signal to the muscle LIM protein (MLP) attached to the terminal part of titin that forms part of the Z-disc complex.⁸ MLP is proposed to be a stretch sensor that transmits the signals that result in the myocyte growth pattern characteristic of volume overload.⁹ This signal system may be defective in a subset of human dilated cardiomyopathy.⁹

Strong and Weak Binding States

Although at a molecular level the events underlying the cross-bridge cycle are complex, a prominent hypothesis holds that cross bridges exist in either a strong or a weak binding state (Fig. 21-6). The arrival of Ca^{2+} at the contractile proteins is a crucial link in *excitation-contraction coupling*. Binding of Ca^{2+} to troponin C shifts the troponin-tropomyosin complex on the actin filament, which permits the myosin heads to form strong binding cross bridges with actin molecules (Fig. 21-6). If, however, the strong binding state were continuously present, the contractile proteins could never relax. Thus it has been proposed that binding of ATP to the myosin head places the cross bridges in a weak binding state even when $[\text{Ca}^{2+}]_i$ is high. Conversely, when ATP is hydrolyzed to ADP and inorganic phosphate (P_i), the strong binding state is again favored (Fig. 21-6). Hence the ATP-induced changes in the molecular configuration of the myosin head result in corresponding variations in its physical properties. Length-dependent activation also promotes the strong binding state (see the section Length-Dependent Activation and the Frank-Starling Effect). Conversely, the weak binding state predominates when $[\text{Ca}^{2+}]_i$ falls and thereby allows relaxation during diastole. As Ca^{2+} dissociates from troponin C during the decline in $[\text{Ca}^{2+}]_i$, the troponin-tropomyosin complex resumes its inhibitory configuration to prevent strong binding.

Actin and Troponin Complex

Although Ca^{2+} provides the essential “on” switch for the cross-bridge cycle by binding to troponin C, this is mediated by a series of interactions between components of the troponin complex, tropomyosin and actin (Fig. 21-6). To understand the role of Ca^{2+} requires a brief description of the molecular structure of actin and the troponin complex. The thin filaments are composed of two helical intertwining actin filaments, with a long tropomyosin molecule that spans seven actin monomers located in the groove between the two actin filaments (see Fig. 21-4). At every seven actin molecules (38.5 nm along this structure) sits a three-protein regulatory *troponin complex*: troponin C (Ca^{2+} binding), I (inhibitory), and T (tropomyosin binding).

When $[\text{Ca}^{2+}]_i$ is low, the tropomyosin molecule is positioned in such a way that it blocks the myosin heads from interacting with actin (see Fig. 21-4). As a result, most cross bridges are in the “blocked position,” although some might visit the weak binding state.⁴ As $[\text{Ca}^{2+}]_i$ increases and binds with troponin C, troponin C binds more tightly to troponin I. This pulls the entire troponin complex (including troponin T) away from tropomyosin (Fig. 21-4), which allows tropomyosin to roll deeper into the thin filament groove,⁴ thereby largely disinhibiting the actin-myosin interaction. Thus weakly bound or blocked cross bridges enter the strongly bound state, and the cross-bridge cycle is initiated. As the strong cross bridges form, they nudge tropomyosin deeper into the actin groove. Tropomyosin contains evolutionarily conserved surface residues that are required for cooperative regulation of actomyosin.⁹ The troponin C–tropomyosin position at one site (open versus closed) also influences its “nearest-neighbor” sites and cooperatively spreads activation along the myofibril.^{2,4}

Myosin and the Molecular Basis of Muscular Contraction

Each myosin head is the terminal part of a heavy chain. The bodies of two of these chains intertwine and each terminates in a short “neck” that carries the elongated myosin head (see Fig. 21-4).

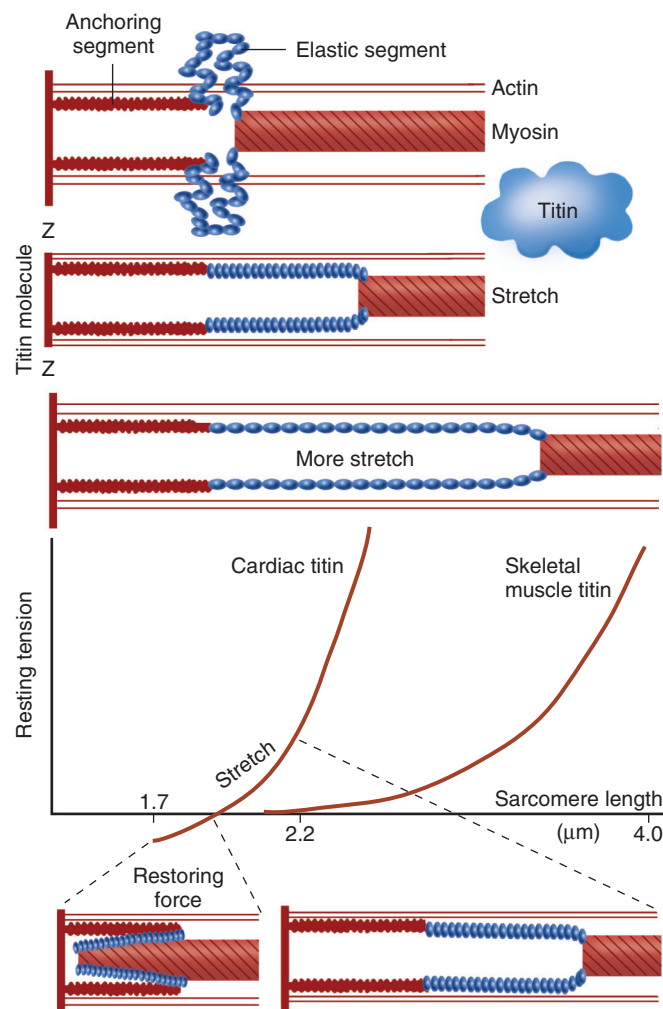

FIGURE 21-5 Titin, a very large elongated protein with elasticity, binds myosin to the Z-line. It may act as a bidirectional spring that develops passive force in stretched sarcomeres and resting force in shortened sarcomeres. As the sarcomere is stretched to its maximum physiologic diastolic length of 2.2 μm (see Fig. 21-18), titin first undergoes straightening (up to 2 μm) and then elongation, the latter rapidly increasing the passive force generated. At low sarcomere lengths, when sarcomeres are slack at approximately the diastolic limit of 1.85 μm (Fig. 21-18), the mechanically active elastic domain is folded on top of itself. At even shorter lengths, which may not be physiologic in an intact heart, substantial restoring force is generated. (Modified with permission of the American Heart Association from Trombitas K, Jian-Ping J, Granzier H: The mechanically active domain of titin in cardiac muscle. *Circ Res* 77:856, 1995; and Helmes M, Trombitas K, Granzier H: Titin develops restoring force in rat cardiac myocytes. *Circ Res* 79:619, 1996.)

FIGURE 21-6 Cross-bridge cycling molecular model updated from the original Rayment five-step model for interaction between the myosin head and the actin filament³ that takes into account other models. The cross bridge (only one myosin head depicted) is pear shaped and consists of the catalytic motor domain, which interacts with the actin molecule, and an extended alpha helical “neck region,” which acts as a lever arm. The nucleotide pocket receiving and binding ATP is a depression near the center of the catalytic domain. The actin binding cleft bisects the catalytic motor domain. During the cross-bridge cycle, the width of the actin binding cleft changes in size, although details remain controversial. Starting with the rigor state (**A**), binding of ATP to the pocket (**B**) is followed by ATP hydrolysis (**C**), which partly closes the actin binding cleft. The cleft opens when phosphate is released (through the cleft rather than through the pocket), and the myosin head strongly attaches to actin to induce the power stroke (**D, E**). During the power stroke the latter rotates about a fulcrum in the region where the helix terminates within the catalytic motor domain. As the head flexes, the actin filament is displaced by approximately 10 nm (**E**). In the process ADP is also released, so the binding pocket becomes vacant. Finally, the rigor state is reached again (**A**) when the myosin head is once more ready to receive ATP to reinitiate the cross-bridge cycle. Throughout, the actin monomer with which the myosin head is interacting is speckled with dots. For references to Cooke, Holmes, and Dominguez, see Opie.⁴ Professor J.C. Rüegg of Heidelberg University, Germany, gave valuable advice.

According to the Rayment model, the base of the head, or the neck, changes configuration in the contractile cycle.⁸ Together with the “bodies” of all the other heads, the myosin thick filament is formed. Each lobe of the bilobed head has an *ATP binding pocket* (also called a nucleotide pocket) and a narrow cleft that extends from the base of this pocket to the actin-binding face.⁹ ATP and its breakdown products ADP and P_i bind to the nucleotide pocket in close proximity to the myosin site where ATP is split to ADP and P_i , (Fig. 21-6). The role of the narrow *actin-binding cleft* that splits the central 50-kDa segment of the myosin head in the contractile cycle is controversial. According to the revised Rayment model,⁴ this cleft responds to binding of ATP or its breakdown products to the nucleotide pocket in such a way that the conformational changes necessary for movement of the head are produced. According to Dominguez and colleagues,⁴ the cleft is closed in the weakly attached states before the power stroke (Fig. 21-6) but opens when P_i is released through the cleft, whereupon the myosin head attaches strongly to actin to induce the power stroke (Fig. 21-6D, E).

Starting with the rigor state (Fig. 21-6A), binding of ATP to its pocket changes the molecular configuration of the myosin head such that the head detaches from actin to terminate the rigor state (Fig. 21-6B). Next, the ATPase activity of the myosin head splits ATP into ADP and P_i , and the head extends (Fig. 21-6C). As ATP is hydrolyzed, the myosin head binds to an adjacent actin unit. P_i is then released from the head through the cleft, and the myosin head is strongly bound to actin (Fig. 21-6D). Next, the head flexes through the power stroke, during which the actin molecule moves by approximately 10 nm,⁴ and the myosin head is now in the rigor state, which is sustained in the absence of ATP. When the pocket releases ADP and binds ATP, the cross bridge releases and the cycle repeats. During isometric (or

isovolumic) contraction the cross bridges rotate but cannot fully move the actin filament, and the stretched strong-binding cross bridges bear force. During shortening (ejection) the actin filament moves during the power stroke.

Each cycle of the cross bridge consumes one molecule of ATP, and this *myosin ATPase activity* is the major site of ATP consumption in the beating heart. Thus when the heart is more strongly activated (see later), the level of ATP consumption is similarly increased.⁴ Each myosin unit consists of two heavy chains with the bodies intertwined and each ending in one head. Notably, during contraction these two heads seem to work via a hand-over-hand action such that the myosin dimer never fully lets go of the thin filament during the activation period.¹⁰ There are two myosin isoforms in cardiac myocytes, alpha and beta, which have similar molecular weight but exhibit substantially different cross-bridge cycle and ATPase rates. The beta myosin heavy chain (β -MHC) isoform exhibits a slower ATPase rate and is the predominant form in adult humans. In small animals (rats and mice), the faster α -MHC form normally predominates but shifts to the β -MHC pattern during chronic stress and heart failure.⁴

Each myosin molecule neck also has two light chains (referred to as *essential* and *regulatory light chains*). The essential myosin light chain (MLC-1) is more proximal to the myosin head and may limit the contractile process by interaction with actin. The *regulatory myosin light chain* (MLC-2) is a potential site for phosphorylation, for example, in response to beta-adrenergic stimulation, and may promote cross-bridge cycling.¹¹ In vascular smooth muscle, which lacks the troponin-tropomyosin complex, contraction is activated by the Ca^{2+} -dependent myosin light chain kinase (MLCK) rather than by Ca^{2+} binding to troponin C (as in striated muscle). Myosin-binding protein C appears to traverse the myosin molecules in the A-band,

thereby potentially tethering the myosin molecules and stabilizing the myosin head with respect to the thick and thin filaments. Defects in myosin, myosin-binding protein C, and several other myofibrillar proteins are genetically linked to familial hypertrophic cardiomyopathy.¹²

Graded Effects of $[Ca^{2+}]_i$ on the Cross-Bridge Cycle

The myofilaments are activated in a graded rather than in all-or-none manner as a function of $[Ca^{2+}]_i$. The dynamics and regulation of Ca^{2+} transients in cardiac myocytes are discussed in the following section, but an important physiologic mechanism for regulating cardiac contractility (e.g., during sympathetic activity) is to increase peak $[Ca^{2+}]_i$ and more fully activate the myofilaments. The higher the $[Ca^{2+}]_i$, the more fully saturated the Ca^{2+} binding sites on troponin C, and consequently more sites are available for cross bridges to form. When more cross bridges are working in parallel, the myocyte (and heart) can develop greater force. There is high cooperativity in this process, in large part because of the “near-neighbor” effect mentioned earlier. That is, Ca^{2+} bound to a single troponin C encourages local cross-bridge formation, and both Ca^{2+} binding and cross-bridge formation directly enhance the likelihood of cross-bridge formation in the 14 actin molecules controlled by one tropomyosin molecule. Furthermore, the openness of that domain directly enhances that of the neighboring domain with respect to both Ca^{2+} binding and cross-bridge formation. This cooperativity means that a small change in $[Ca^{2+}]_i$ can have a large effect on the strength of contraction.

Length-Dependent Activation and the Frank-Starling Effect

Besides $[Ca^{2+}]_i$, the other major factor influencing the strength of contraction is sarcomere length at the end of diastole, just before the onset of systole. Both Otto Frank and Ernest Starling observed that the strength of the heartbeat was greater the more the diastolic filling of the heart. The increased heart volume translates into increased sarcomere length, which acts by a length-sensing mechanism.⁴ A part of this *Frank-Starling effect* has historically been ascribed to increasingly optimal overlap between the actin and myosin filaments. However, it has become clear that there is also a substantial increase in myofilament Ca^{2+} sensitivity with an increase in sarcomere length.⁴ A plausible mechanism for this regulatory change may reside in the decreasing interfilament spacing as the heart muscle is stretched.⁴ That is, the myocyte is at constant volume (over the cardiac cycle), so as the cell shortens, it must thicken, and conversely, when it is stretched, the cell gets thinner and filament spacing becomes narrower. This attractive lattice-dependent explanation for the Frank-Starling relationship has been challenged by the careful x-ray diffraction studies of de Tombe's group.⁴ They found that reducing sarcomere lattice spacing by osmotic compression failed to influence myofilament Ca^{2+} sensitivity. Although several mechanisms could contribute to the Ca^{2+} sensitization of the myofilament at longer length, the issue is unresolved.

When changes in diastolic length (or preload) are the cause of altered contractile strength, it is said to be a Frank-Starling (or sometimes just Starling) effect. Conditions in which contraction is strengthened (or weakened) independent of sarcomere length (e.g., increased Ca^{2+} transient amplitude) are referred to as positive (or negative) inotropic states or enhanced (or reduced) contractility. The distinction between these heterometric and homeometric mechanisms of altered cardiac strength is important.

Cross-Bridge Cycling Differs from the Cardiac Contraction-Relaxation Cycle

The cardiac cycle of Wiggers (see later) must be distinguished from the cross-bridge cycle.⁴ The former reflects the overall changes in pressure in the left ventricle, whereas the latter cycle is the repetitive interaction between myosin heads and actin. During isovolumic contraction (before aortic valve opening), the sarcomeres do not shorten appreciably, but cross bridges are developing force—not all

simultaneously, however. That is, at any given moment some myosin heads will be flexing or flexed (resulting in force generation), some will be extending or extended, and some will be attached weakly to actin and some detached from actin. Numerous such cross-bridge cycles, each lasting microseconds, are integrated to produce the resulting force (and pressure). When ventricular pressure (sum of cross-bridge forces) reaches aortic pressure (afterload), ejection begins and is associated with the cross bridges actively moving the thin actin filaments toward the central area of the thick myosin filaments, thereby shortening the sarcomere. Note that as ejection proceeds (and sarcomeres shorten), myofilament Ca^{2+} sensitivity declines. Thus both $[Ca^{2+}]_i$ decline and shortening cause a progressive decline in the contractile state as systole gives way to diastole. Both the Ca^{2+} transient properties and the myofilament Ca^{2+} sensitivity and cross-bridge cycling rate are altered under physiologic conditions (such as sympathetic stimulation and local acidosis or ischemia), which is discussed below and elsewhere.

Force Transmission

Volume and pressure overload may owe their different effects on myocardial growth to different patterns of force transmission.⁴ Whereas increased diastolic force is transmitted longitudinally via titin to reach the MLP protein, the postulated sensor (see the earlier section Titin and Length Sensing), increased systolic force may be transmitted laterally (i.e., at right angles) via the Z-disc and cytoplasmic actin to reach the cytoskeletal proteins and cell-to-matrix junctions such as the focal adhesion complex. How this mechanical force becomes translated into signals that activate the growth pathways such as those leading to mitogen-activated protein kinase (MAPK) and/or altered gene regulation and cell size and shape is addressed in other chapters.

Contractile Protein Defects and Cardiomyopathy

Genetic-based hypertrophic and dilated cardiomyopathies not only produce hearts that look and behave very differently but also have diverse molecular causes. These cardiomyopathies are in general linked to mutant genes that cause abnormalities in the force-generating system, such as β -MHC, troponin (T, I, and C), MLCs, myosin-binding protein C, and α -tropomyosin (see Chapter 65). One hypothesis is that mutations that increase contractile performance and/or energy demand result in concentric hypertrophy¹³ whereas mutations that either reduce force generation or result in non-force-generating cytoskeletal proteins (e.g., dystrophin, nuclear lamin, cytoplasmic actin, and titin) lead to a dilated cardiomyopathy. However, although the distinction between the two types of cardiomyopathy remains useful, it is oversimplified, with several examples of overlapping mechanisms.

CALCIUM ION FLUXES IN THE CARDIAC CONTRACTION-RELAXATION CYCLE

Calcium Movements and Excitation-Contraction Coupling

Ca^{2+} has a crucial role in regulating the contraction and relaxation phases of the cardiac cycle. Details of the associated Ca^{2+} fluxes that link contraction to the wave of excitation (*excitation-contraction coupling*) are now reasonably well clarified and accepted.^{2,4} Relatively small amounts of Ca^{2+} (*trigger Ca^{2+}*) actually enter and leave the cardiomyocyte during each cardiac cycle, whereas larger amounts move in and out of the SR (Fig. 21-7). Each action potential depolarization traveling down the T tubules opens the voltage-gated L-type Ca^{2+} channels that are physically near the part of the SR lying close to the T tubule and activates SR Ca^{2+} release channels (RyRs). In this *Ca^{2+} -induced Ca^{2+} release* mechanism, a smaller amount of Ca^{2+} entering via the Ca current (I_{Ca}) triggers the release of a relatively large amount of Ca^{2+} into the cytosol.^{2,4} In the human ventricle, SR Ca^{2+} release is three to four times higher than Ca^{2+} influx via I_{Ca} (in rat and mouse myocytes, amplification is two to three times higher).² These

FIGURE 21-7 Calcium fluxes in the myocardium. Crucial features are (1) entry of Ca^{2+} via the voltage-sensitive L-type Ca^{2+} channels, which act as a trigger for the release of Ca^{2+} from the SR; (2) the effect of beta-adrenergic stimulation with adenylyl cyclase to form cAMP, the latter helping open the Ca^{2+} channel and increase the rate of uptake of Ca^{2+} into the SR; and (3) exit of Ca^{2+} ions chiefly via Na/Ca exchange, with the sodium pump thereafter extruding the Na^{+} ions thus gained. The latter process requires ATP. Note the much higher extracellular (mM) than intracellular cytosolic $[\text{Ca}^{2+}]$ ($< \mu\text{M}$) and much higher $[\text{Ca}^{2+}]$ in the SR. Mitochondria can act as a buffer against excessive changes in the free cytosolic calcium concentration. (From Opie LH: *Heart Physiology, from Cell to Circulation*. Lippincott, Williams & Wilkins, 2004. Figure copyright D.M. Bers and L. H. Opie. Philadelphia, Opie, © 2004; also see Bers DM: *Cardiac excitation-contraction coupling*. *Nature* 415:198, 2002.)

Ca^{2+} fluxes elevate $[\text{Ca}^{2+}]_i$ and promote binding of Ca^{2+} to troponin C and hence activation of the contractile process.

Ca²⁺ Release and Uptake by the Sarcoplasmic Reticulum

Sarcoplasmic Reticulum Network and Ca²⁺ Movements

Electron microscopic studies show that the SR is a continuous network surrounding the myofilaments with connections across Z-lines and transversely between myofibrils. There is direct functional evidence of continuity of the lumina of the entire SR network and nuclear envelope in adult cardiac myocytes. This allows relatively rapid diffusion of Ca^{2+} within the SR to balance free $[\text{Ca}^{2+}]$ within the SR ($[\text{Ca}^{2+}]_{\text{SR}}$).¹⁴ The total SR Ca^{2+} content is the sum of $[\text{Ca}^{2+}]_{\text{SR}}$ plus substantially more bound to the intra-SR Ca^{2+} buffer calsequestrin. It is critical to both normal cardiac function and electrophysiology, and abnormalities contribute to systolic and diastolic dysfunction and arrhythmias. $[\text{Ca}^{2+}]_{\text{SR}}$ dictates the SR Ca^{2+} content, the driving force for release of Ca^{2+} , and regulates RyR release channel gating.

Junctional Sarcoplasmic Reticulum and Ryanodine Receptor

The RyR channels that mediate release of Ca^{2+} from the SR are located at specialized junctions between the T tubule plasma membrane and the jSR membrane.^{2,4} Each junction has 50 to 250 RyR channels on the jSR that are directly under a cluster of 20 to 40 sarcolemmal L-type Ca^{2+} channels across a 15-nm junctional gap (that is actually crowded with protein). RyR2 (to denote the cardiac isoform) functions both as a Ca^{2+} channel and as a scaffolding protein that localizes numerous key regulatory proteins to the jSR.^{2,4} On the large cytosolic side, these include proteins that can stabilize RyR gating (e.g., calmodulin [CaM]; FK-506 binding protein [FKBP-12.6]); kinases that can regulate RyR gating by phosphorylation (e.g., protein kinase A [PKA] and Ca^{2+} /CaM-dependent protein kinase II [CaMKII]); and the protein phosphatases PP1 and PP2A, which dephosphorylate the RyR (Fig. 21-8).

Inside the SR the RyR also couples to several proteins (e.g., junctin, triadin, and via them calsequestrin) that similarly regulate RyR gating and, in the case of calsequestrin, provides a local reservoir of buffered Ca^{2+} close to the release channel. The actual RyR channel is made up of a symmetric tetramer of RyR molecules, each of which may have the aforementioned regulatory proteins associated with it. Thus the RyR receptor complex is very large (>7000 kDa; Fig. 21-8).¹⁵ When the T tubule is depolarized, one or more L-type Ca^{2+} channels open, and local cleft $[\text{Ca}^{2+}]$ increases sufficiently to activate at least one local jSR RyR (multiple channels here ensure high-fidelity signaling). The Ca^{2+} released from these first openings recruit additional RyRs in the junction via Ca^{2+} -induced Ca^{2+} release to amplify release of Ca^{2+} into the junctional space. The Ca^{2+} diffuses out of that space throughout the sarcomere to activate contraction. Each of the approximately 20,000 jSR regions in the typical ventricular myocyte seems to function independently in response to local activation by I_{Ca} . Thus the global Ca^{2+} transient in the myocyte at each beat is the spatiotemporal summation of SR Ca^{2+} release events from thousands of jSR regions, synchronized by the upstroke of the action potential and activation of I_{Ca} .

Turning off Ca²⁺ Release:

Breaking Positive Feedback

Ca^{2+} -induced Ca^{2+} release is a positive feedback process, but it is now known that SR Ca release turns off when $[\text{Ca}]_{\text{SR}}$ drops by approximately 50% (i.e., from a diastolic value of ≈ 1 mM to a nadir of ≈ 400 μM).¹³ Elegant studies have documented how I_{Ca} is inactivated by high local $[\text{Ca}^{2+}]$, and this robust Ca-dependent inactivation is mediated by binding of Ca^{2+} to the CaM that is already associated with that channel. When Ca^{2+} binds to CaM, it alters channel conformation such that inactivation is favored. I_{Ca} is also subject to voltage-dependent inactivation during the action potential plateau, and thus inactivation limits further entry of Ca^{2+} into the cell.

As for Ca^{2+} -dependent RyR activation, several mechanisms may contribute to breaking its inherent positive feedback. First but not necessarily most compelling is analogous to Ca^{2+} -CaM-dependent inactivation of I_{Ca} . That is, binding of Ca^{2+} to CaM that is prebound to RyR2 favors closure of the channel and inhibits reopening (Fig. 21-8).¹⁶ Second and undoubtedly important is that RyR2 gating is also sensitive to luminal $[\text{Ca}^{2+}]_{\text{SR}}$ such that high $[\text{Ca}^{2+}]_{\text{SR}}$ favors opening and low $[\text{Ca}^{2+}]_{\text{SR}}$ favors closure.¹⁷ Indeed, release of Ca^{2+} from the SR during normal Ca^{2+} transients is robustly turned off when $[\text{Ca}^{2+}]_{\text{SR}}$ falls to approximately half its normal value (≈ 400 μM , still 500 times higher than $[\text{Ca}]_i$), almost regardless of the rate of SR Ca^{2+} release.^{13,14} A third and related factor is that as release proceeds and $[\text{Ca}^{2+}]_{\text{SR}}$ declines, Ca^{2+} flux through the RyR falls and junctional $[\text{Ca}^{2+}]$ also falls, all of which tend to disrupt the positive feedback. That is, the RyR is less sensitive to activating Ca^{2+} (because $[\text{Ca}^{2+}]_{\text{SR}}$ is low) and $[\text{Ca}^{2+}]$ on the activating side is also weaker.¹⁸

Calmodulin: A Versatile Mediator of Ca²⁺ Signaling

CaM has four Ca^{2+} binding sites, resembles troponin C, and participates in many different cellular pathways from ion channels to transcriptional regulation.¹⁶ In many cases (e.g., L-type Ca^{2+} , Na^{+} , and some K^{+} channels and RyR and inositol 1,4,5-triphosphate receptors), CaM is already prebound or “dedicated” such that elevation of local $[\text{Ca}^{2+}]_i$ can rapidly induce Ca^{2+} -CaM effects on their targets (Fig. 21-9).^{19,20} Indeed, more than 90% of the CaM in myocytes is already bound to cellular targets before Ca^{2+} binds to and activates it. Nevertheless, many myocyte CaM targets (e.g., CaMKII, calcineurin, nitric oxide synthase [NOS]) compete for this limited pool of “promiscuous” CaM. Thus CaM signaling in myocytes is complex and is further complicated by the effects of CaMKII, which influences some of the same targets and processes as CaM itself does.^{16,20}

FIGURE 21-8 Role of RyR in calcium-induced calcium release. The RyR protein forms a link between the T tubule and the SR and is a scaffolding protein (which binds other proteins such as kinases and phosphatases). This makes a macromolecular complex, also called the “foot” region. One high-affinity RyR is composed of four RyR monomer proteins. The molecular model of one RyR is schematically shown in the **right panel**. The four RyR proteins make a single calcium release channel, in a manner similar to the formation of some other ion channels (schematic, **left panel**). Depolarization stimulates the L-type Ca channel of the T tubule to allow the entry of calcium ions. The incoming Ca binds to the RyR, which causes molecular conformational changes that result in opening of the calcium release channel and release of calcium from the SR. CaM/K = calmodulin or calmodulin kinase. (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. 4th ed. Philadelphia, Lippincott, Williams & Wilkins, 2004.)

FIGURE 21-9 Role of CaM and its kinase in regulating intracellular $[Ca^{2+}]$. The rising cytosolic Ca^{2+} concentration in systole activates the Ca^{2+} regulatory system whereby Ca^{2+} -CaM causes inactivation of L-type Ca^{2+} current and RyR current. This negative feedback system limits cellular Ca^{2+} gain. The effects of CaMKII can also modulate these systems.¹⁹ For example, (1) CaMKII limits the extent of Ca^{2+} -dependent inactivation and enhances Ca^{2+} current amplitude, (2) it increases the fraction of SR Ca^{2+} released from the RyR in response to the Ca^{2+} current trigger (which can be arrhythmogenic), (3) it phosphorylates PLB to enhance SR Ca^{2+} uptake by SERCA, and (4) it can modulate Na^{+} and K^{+} channel gating in ways that are also proarrhythmic.^{19,20}

Calcium Sparks and Waves

In addition to SR Ca^{2+} release triggered by I_{Ca} during normal excitation-contraction coupling, there is a finite probability that a given RyR will open stochastically. Because of local Ca^{2+} -induced Ca^{2+} release in the junctional cleft, this can lead to spontaneous local SR Ca^{2+} release events known as Ca^{2+} sparks.^{18,21} Under normal resting conditions these Ca^{2+} sparks have a low probability ($\approx 10^{-4}$), which means that at any moment there might be one or two Ca^{2+} sparks per myocyte. Because local $[\text{Ca}^{2+}]_i$ declines rapidly as Ca^{2+} diffuses away from the initiating cleft, the resulting local $[\text{Ca}^{2+}]_i$ at the next cleft (1 to 2 μm away) is normally too low to trigger that neighboring site. Thus Ca^{2+} sparks are very local events (within 2 μm in the cell). However, the probability of Ca^{2+} sparks is greatly enhanced when $[\text{Ca}^{2+}]_i$ or $[\text{Ca}^{2+}]_{\text{SR}}$ is elevated or under conditions in which the RyR is otherwise sensitized (e.g., by oxidation or CaMKII). These conditions can greatly enhance the likelihood that SR Ca^{2+} release from one junction will be sufficient to trigger neighboring junctions 1 to 2 μm away and result in propagating Ca^{2+} waves throughout the whole myocyte. These Ca^{2+} waves can be arrhythmogenic. First, the Ca^{2+} wave can activate substantial inward current via $\text{Na}^+/\text{Ca}^{2+}$ exchange (NCX; see later), which can depolarize the membrane potential and contribute to both early and delayed afterdepolarizations (EADs and DADs) during the action potential plateau or during diastole, respectively. EADs result in prolongation of the action potential duration, and DADs can initiate premature ventricular contractions (PVCs).

Calcium Uptake into the Sarcoplasmic Reticulum by SERCA

Ca^{2+} is transported into the SR by SERCA, which constitutes almost 90% of the SR protein. Its molecular weight is approximately 115 kDa, and it straddles the SR membrane in such a way that part of it protrudes into the cytosol. Several isoforms exist, but in cardiac myocytes the dominant form is SERCA2a. For each molecule of ATP hydrolyzed by this enzyme, two calcium ions are taken up and accumulate within the SR (Fig. 21-10; also see Fig. 21-9). The source of the energy is at least in part derived from cytosolic generation of ATP via glycolysis.¹ SR Ca^{2+} uptake is the primary driver of cardiac myocyte relaxation, and reuptake starts as soon as $[\text{Ca}^{2+}]_i$ begins to rise. Because Ca^{2+} removal is slower than Ca^{2+} influx and release, a characteristic rise and fall in $[\text{Ca}^{2+}]_i$ called the Ca^{2+} transient takes place. As $[\text{Ca}^{2+}]_i$ falls, Ca^{2+} dissociates from troponin C and this progressively switches off the myofilaments. A reduction in SERCA expression or

function (as seen in heart failure or energetic limitations) can thus directly result in slower rates of cardiac relaxation. In addition, the strength of SR Ca^{2+} uptake directly influences the diastolic SR Ca^{2+} content and $[\text{Ca}^{2+}]_{\text{SR}}$, which dictates both the sensitivity of the RyR and the flux rate of SR Ca^{2+} release. Thus SR Ca^{2+} uptake and release are an integrated system.

Phospholamban (PLB) was so named by its discoverers Tada and Katz to mean “phosphate receiver.”²³ PLB binds directly to SERCA2a, and under basal conditions this reduces the affinity of SERCA for cytosolic Ca^{2+} , which results in weaker SR Ca^{2+} uptake at any given $[\text{Ca}^{2+}]_i$. However, when PLB is phosphorylated by either PKA or CaMKII (at Ser16 or Thr17, respectively), the inhibitory effect is relieved, thereby resulting in increased rates of SR Ca^{2+} uptake, cardiac relaxation (*lusitropic effect*), and increased SR Ca^{2+} content, which drives stronger contraction (*inotropic effect*; Fig. 21-10).

The Ca^{2+} taken up into the SR is stored within the SR before further release. The highly charged low-affinity Ca^{2+} buffer ($K_d \approx 600 \mu\text{M}$) *calsequestrin* is found primarily at the jSR and enhances the local availability of Ca for release via the nearby RyR. *Calreticulin* is another Ca^{2+} -storing protein that is similar in structure to calsequestrin and probably similar in function. There is also evidence that calsequestrin and two other proteins located in the SR membrane (junctin and triadin) may regulate the properties of the RyR and be part of the mechanism by which higher $[\text{Ca}]_{\text{SR}}$ enhances RyR opening.¹⁷ Reuptake by SERCA occurs everywhere in the SR membrane in the network that surrounds the myofilaments. Diffusion of Ca^{2+} within the SR is relatively fast, which allows restoration of $[\text{Ca}^{2+}]_{\text{SR}}$ at the jSR to occur quickly as Ca^{2+} is taken back up everywhere.²⁴ Indeed, during normal Ca^{2+} release, intra-SR Ca^{2+} diffusion is rapid enough to limit Ca^{2+} gradients between SR release sites in the jSR and the Ca^{2+} uptake sites. This diffusion also ensures that $[\text{Ca}^{2+}]_{\text{SR}}$ is relatively uniform throughout the myocyte, which facilitates the uniformity of SR Ca^{2+} release and myofibril activation throughout the cell.

SARCOLEMMAL CONTROL OF Ca^{2+} AND Na^+

Calcium and Sodium Channels

Excitation-contraction coupling is initiated by voltage-induced opening of the sarcolemmal L-type Ca^{2+} channels. The channels are pore-forming macromolecular proteins that span the sarcolemmal lipid bilayer to allow a highly selective pathway for transfer of ions into the heart cell when the channel changes from a closed to an open state. Ion channels have two major properties: gating and permeation. Ca^{2+} and Na^+ channels have two functional “gates,” activation and inactivation gates. At the normal resting membrane potential the activation gate is closed and the inactivation gate is open, so the channels are available to open on depolarization in their characteristic *voltage-gated* manner. On activation the inactivation gate starts to close, and the kinetics of inactivation depends on voltage, time, and local $[\text{Ca}^{2+}]_i$. Recovery from inactivation (which makes the channels available for activation again) is also time, voltage, and Ca^{2+} dependent. Thus after the action potential recovers, time is required for the Ca^{2+} and Na^+ channels to recover from inactivation.

Permeation (or conductance) refers to the actual flow of ions or current through the open channel. Ca^{2+} and Na^+ channels are highly selective for Ca^{2+} and Na^+ , respectively, relative to other physiologic ions. However, nonphysiologic ions can also permeate; Ba^{2+} and Sr^{2+} readily permeate Ca^{2+} channels, and Li^+ permeates Na^+ channels, and these ions are sometimes used experimentally to study I_{Ca} and I_{Na} . The concentration of the permeant ion influences the conductance, and in simple Ohm's law terms ($\text{I}_{\text{Ca}} = g_{\text{Ca}}[\text{E}_m - \text{E}_{\text{Ca}}]$), current is the product of conductance (g_{Ca}), which depends on gating, and permeation times the electrochemical driving force ($\text{E}_m - \text{E}_{\text{Ca}}$), which is the difference between the membrane potential (E_m) and the potential that exactly counterbalances the transmembrane $[\text{Ca}^{2+}]$ gradient (E_{Ca} , typically +120 mV but changes as $[\text{Ca}]_i$ changes).

FIGURE 21-10 Ca^{2+} uptake into the SR by SERCA2a. An increased rate of uptake of Ca^{2+} into the SR enhances the rate of relaxation (*lusitropic effect*). PLB, when phosphorylated (P), removes the inhibition exerted on the Ca^{2+} pump by its dephosphorylated form. Thereby, Ca^{2+} uptake is increased either in response to enhanced cytosolic $[\text{Ca}^{2+}]_i$ or in response to beta-adrenergic agonists or CaMKII activation (which can be secondary to the beta-adrenergic system).^{2,20,22}

Thus depolarization activates both Ca^{2+} and Na^{+} channels but also decreases the driving force for the currents.

Molecular Structure of Ca^{2+} and Na^{+} Channels

Both Ca^{2+} and Na^{+} channels contain a major α subunit with four transmembrane domains (I to IV), and each domain has six transmembrane helices (S1 to S6) and a pore loop between S5 and S6.^{1,2} Each channel also has associated auxiliary subunits ($\alpha 2\delta$, β , and γ for Ca^{2+} channels) that may influence trafficking and gating. Activation is now understood in molecular terms as outward movement of the charged S4 transmembrane segment (called the *voltage sensor*) in each of the four domains of Na^{+} and Ca^{2+} channels.¹ This S4 voltage dependence differs among channels, and Na^{+} channels are activated at more negative E_m than Ca^{2+} channels are. *Inactivation* is more complex and involves multiple channel domains, and channels accumulate in this state during prolonged depolarization. The open state is typically the last of a sequence of multiple molecular closed conformations. However, there is typically a binary switch between closed and open such that the single-channel conductance is either near zero or at a constant open conductance. This stochastic nature means that it is often better to speak of the *probability of channel opening*.

T- Versus L-Type Ca^{2+} Channels

The cardiovascular system has two major types of sarcolemmal Ca^{2+} channels, T-type and L-type channels. T (transient)-type channels open at a more negative voltage, have short bursts of opening, and do not interact with conventional Ca^{2+} antagonist drugs.¹ In adult ventricular myocytes there does not seem to be appreciable T-type I_{Ca} (except under pathophysiologic conditions). Even when T-type channels are expressed in ventricular myocytes they do not seem to target to the regions where RyRs are, and consequently they do not participate in excitation-contraction coupling per se. However, measurable T-type I_{Ca} is present in neonatal ventricular myocytes, Purkinje fibers, and some atrial cells (including pacemaker cells). In these locations the negative activation voltages may allow T-type I_{Ca} to contribute to pacemaker function. So in ventricular myocytes, L-type currents predominate.

L-Type Ca^{2+} Channel Localization and Regulation

L (long-lasting) channels are concentrated in the T tubules at jSR sites, where they are positioned for Ca^{2+} -induced Ca^{2+} release from the RyR. A fraction of L-type Ca^{2+} channels are also localized in caveolae, where they may participate in local Ca^{2+} signaling, which is somewhat distinct from triggering of SR Ca^{2+} release. L-type Ca^{2+} channels are inhibited by Ca^{2+} channel blockers such as verapamil, diltiazem, and the dihydropyridines. I_{Ca} is rapidly activated during the rising phase of the action potential, but the combination of Ca^{2+} influx via I_{Ca} itself and local SR Ca^{2+} release causes rapid Ca^{2+} -dependent inactivation of I_{Ca} . Voltage-dependent inactivation also contributes to the decline in I_{Ca} during the action potential, but some amount of I_{Ca} continues throughout the action potential.²⁵ Inward I_{Ca} is an important contributor to the plateau phase of the cardiac action potential, and excess I_{Ca} or failure of inactivation can prolong the duration of the action potential.

During beta-adrenergic stimulation, cyclic adenosine monophosphate (cAMP) and PKA activity increases and results in phosphorylation of the Ca^{2+} channel and alteration of its gating properties. Notably, most of the molecular components of this beta-adrenergic receptor-cAMP-PKA and phosphatase pathway are localized right at the L-type Ca^{2+} channel, which facilitates rapid sympathetic activation of changes in I_{Ca} . PKA-dependent phosphorylation of the channel shifts activation (and inactivation) to more negative voltages and increases the open time of the channel. This combination can greatly increase I_{Ca} , which can increase both the fraction of SR Ca^{2+} release and the Ca^{2+} load of the cell and SR (to further enhance the Ca^{2+} transient amplitude and inotropic state).

Sodium Channels

Voltage-gated cardiac Na^{+} current (I_{Na}) is carried mainly by the Nav1.5 cardiac isoform, but there is a minor component ascribable to several

other isoforms that are *neuronal* isoforms. The Nav1.5 channels seem to be especially concentrated at the ends of the myocyte near intercalated discs, but the overall density of I_{Na} is relatively uniform between the T tubule and surface membrane.²⁶ Depolarization activates I_{Na} , and peak I_{Na} is very large and drives the upstroke of the cardiac action potential. Voltage-dependent inactivation of I_{Na} is very rapid, and under normal conditions, Na^{+} channels inactivate within a very few milliseconds of depolarization. However, a very small number of Na^{+} channels remain open (or reopen), thereby creating a small but persistent influx of Na^{+} throughout the plateau of the action potential. This so-called late sodium current (I_{NaL}) is characterized by ultraslow, voltage-independent inactivation and reactivation.²⁷ Although the amplitude of I_{NaL} is small (<1% of peak I_{Na}), because peak I_{Na} is so large, this I_{NaL} still constitutes a significant inward current during the plateau phase of the action potential. Under pathophysiologic conditions the amount of I_{NaL} can increase significantly, and this can result in acquired long-QT (LQT) syndrome and also cause Na^{+} and Ca^{2+} loading of myocytes, which carries additional arrhythmogenic potential. Thus I_{NaL} has emerged as a potentially important therapeutic target.^{19,28}

Ca^{2+} /Calmodulin-Dependent Protein Kinase II Alters Gating of I_{Na} , I_{Ca} , and Other Channels

CaMKII is known to be upregulated and chronically activated in numerous pathophysiologic conditions (e.g., ischemia-reperfusion, heart failure, ROSS). It has also been shown that CaMKII-dependent Na^{+} channel phosphorylation causes increased I_{NaL} , which may produce an acquired form of LQT3 syndrome in patients with genetically normal Na^{+} channels (see Fig. 21-9).^{19,28} At the same time, CaMKII also shifts Na^{+} channel availability to more negative voltages, enhances intermediate inactivation, and slows recovery from inactivation, all loss-of-function effects that could cause an acquired Brugada syndrome-like condition. Indeed, this can foster both phenotypes, depending on the heart rate: LQT syndrome at a lower heart rate and Brugada syndrome at a higher heart rate.¹⁹ CaMKII also modulates Ca^{2+} and K^{+} channel currents, and this can further promote arrhythmogenesis by enhancing the transmural dispersion of repolarization.¹⁹

Ion Exchangers and Pumps

To maintain steady-state Ca^{2+} and Na^{+} balance, the amount of Ca^{2+} and Na^{+} entering during each action potential must be exactly balanced by efflux before the next beat. This is the definition of steady state. For Ca^{2+} , NCX is responsible for extruding most of the Ca^{2+} that entered via I_{Ca} and NCX, whereas a minor fraction is extruded by the plasma membrane Ca^{2+} -ATPase (PMCA). NCX uses the inward $[\text{Na}^{+}]$ electrochemical gradient from 3 Na^{+} ions to pump each Ca^{2+} ion into the extracellular space against a large electrochemical gradient (and PMCA uses 1 ATP to pump each Ca^{2+} ion). The main mechanism for extruding Na^{+} from the cell is Na^{+} , K^{+} -ATPase, which pumps 3 Na^{+} ions out for each ATP consumed. Note that NCX also indirectly uses the energy from Na^{+} , K^{+} -ATPase to perform its function.

Sodium-Calcium Exchanger

During relaxation, SR Ca^{2+} -ATPase and NCX compete for the removal of cytosolic Ca^{2+} , with the SR pump normally being dominant.^{2,4} NCX is reversible, so the direction of Ca^{2+} flux depends on the membrane potential and $[\text{Na}^{+}]$ and $[\text{Ca}^{2+}]$ on both sides of the sarcolemma. The E_m in which the inward electrochemical potential is the same for 3 Na^{+} ions as for 1 Ca^{2+} ion to enter is the *reversal or equilibrium potential* (E_{NCX} , similar to that for ion channels). When E_m is higher than this voltage, entry of Ca^{2+} is favored, whereas for E_m below E_{NCX} , the Ca^{2+} efflux mode is thermodynamically favored. During diastole ($E_m = -80$ mV), NCX normally extrudes Ca^{2+} , but because $[\text{Ca}^{2+}]_i$ is low during diastole, the Ca^{2+} flux rate is low (low substrate concentration). As the action potential rises to a peak, E_m normally exceeds E_{NCX} and Ca^{2+} influx is favored, but this occurs only briefly because the high local $[\text{Ca}^{2+}]$ near the membrane drives NCX back into the Ca^{2+} extrusion mode. When the action potential repolarizes, the

negative E_m further enhances the Ca^{2+} extrusion flux, and at this time $[\text{Ca}^{2+}]_i$ is above the diastolic level, so NCX can transport Ca^{2+} effectively. Note that if SR Ca^{2+} release is small and/or I_{Ca} is small or $[\text{Na}^+]_i$ is abnormally high (as occurs in heart failure), NCX can continue to bring Ca^{2+} into the cell during much of the action potential duration and in that sense can partially compensate for the lack of I_{Ca} or SR Ca^{2+} release.² NCX is also allosterically activated by increasing $[\text{Ca}^{2+}]_i$.²⁹ Although such regulation takes several seconds to occur, it may provide a mechanism to enhance the cell's ability to extrude Ca^{2+} when $[\text{Ca}^{2+}]_i$ is chronically high, as well as to keep NCX from driving $[\text{Ca}^{2+}]_i$ and indirectly $[\text{Ca}^{2+}]_{\text{SR}}$ to inappropriately low levels when cytosolic Ca^{2+} is in short supply.

Under normal conditions in human or rabbit ventricular myocytes, the steady-state condition occurs when the relative Ca^{2+} removal from the cytosol by SERCA and NCX is 70% to 75% and 20% to 25%, respectively (with PMCA contributing $\leq 1\%$). In heart failure, in which SERCA is downregulated and NCX may be upregulated, the SERCA and NCX contributions are closer to the same. In the mouse and rat ventricle the difference is larger (92% SERCA, 7% NCX). Of course, the way that this steady state comes about involves all of the various Ca^{2+} transport systems dynamically, but the relative rates of Ca^{2+} flux via SERCA and NCX at physiologic $[\text{Ca}^{2+}]_i$ provide a good estimate. These removal fluxes must also pertain to the integrated Ca^{2+} fluxes into the cytosol. That is, the combination of Ca^{2+} entry via I_{Ca} and NCX in human and mouse ventricle would be 20% to 25% or 8%, respectively. Looking at this another way, amplification of the Ca^{2+} transient by SR Ca^{2+} release is only approximately 4-fold for human or rabbit ventricle (and less in heart failure) but approximately 12-fold for mouse or rat ventricle.

Heart Rate and $\text{Na}^+/\text{Ca}^{2+}$ Exchange

NCX participates in the force-frequency relationship (Treppe or Bowditch phenomenon).⁴ An increasing heart rate (independent of sympathetic activation) increases the amount of Na^+ and Ca^{2+} entry per unit time and also diminishes the time available for extrusion of Na^+ and Ca^{2+} . Of course this will tend to increase the amount of Ca^{2+} in the SR simply because of more frequent I_{Ca} pulses and less time for removal of Ca^{2+} from the cell. However, the same thing happens for Na^+ , and the elevation in $[\text{Na}^+]_i$ also limits the ability of NCX to extrude Ca^{2+} , which further increases the amount of Ca^{2+} in the myocyte and SR when the cell achieves a new steady state. This NCX effect (once referred to as the “sodium pump lag” hypothesis) thus amplifies the intrinsic inotropic effect of an increase in heart rate.

Sodium Pump (Na^+/K^+ -Adenosine Triphosphatase)

During the normal heartbeat, Na^+ enters the myocyte mainly via Na^+ channels and NCX, with NCX being quantitatively most important.²² Na^+/H^+ exchange also mediates significant Na^+ influx, particularly when cells are acidotic. In the steady state this Na^+ influx is matched by an equal Na^+ efflux, mediated mainly via sarcolemmal Na^+/K^+ -ATPase, or the Na^+ pump. The Na^+ pump is activated by internal Na^+ or external K^+ and transports 3 Na^+ ions out and 2 K^+ ions in per ATP molecule used. During this process, one positive charge leaves the cell, and thus Na^+/K^+ -ATPase is electrogenic and carries an outward current.⁴ Na^+/K^+ -ATPase in the heart is modulated by the endogenous accessory protein phospholemman (PLM), which works in a manner analogous to the PLB-SERCA2a mechanism. That is, at baseline PLM reduces the intracellular Na^+ affinity of Na^+/K^+ -ATPase, but when it is phosphorylated (by either PKA or protein kinase C [PKC]), that inhibitory effect is relieved.²² Thus during sympathetic activation, Na^+/K^+ -ATPase activity is increased at any given $[\text{Na}^+]_i$ to better keep up with the higher rates of Na^+ influx that occur under this condition.

Digitalis glycosides inhibit Na^+/K^+ -ATPase and have been used for more than 200 years as a cardiac inotropic drug for the treatment of heart failure (although their use has diminished in recent years). Partial inhibition of Na^+/K^+ -ATPase causes an increase in $[\text{Na}^+]_i$ in myocytes, and this limits the ability of NCX to extrude Ca^{2+} , which results in enhanced myocyte and SR Ca^{2+} loading and release. A limitation with this approach is that there is a narrow therapeutic range and too much inhibition can lead to myocyte Ca^{2+} overload and trigger arrhythmias.

However, this emphasizes the close interrelationship between Na^+ and Ca^{2+} regulation mediated by the powerful NCX that is present in cardiac myocytes.

ADRENERGIC SIGNALING SYSTEMS

Physiologic Fight-or-Flight Response

During the classic adrenergic fight-or-flight response, cardiac myocyte beta-adrenergic receptors are activated, which leads to increased cAMP production and PKA activation and consequent phosphorylation and altered function of numerous myocyte targets as discussed below. This results in an increase in the heart rate (*positive chronotropy*), increased contractility (*positive inotropy*), faster cardiac relaxation (*positive lusitropy*), and enhanced conduction velocity through the conduction system (*positive dromotropy*). These events enhance cardiac output by enhancing the heart rate, stroke volume, and diastolic filling. Thus this is a key physiologic mechanism for increasing cardiac output in response to increased metabolic and hemodynamic demands.

During the adrenergic response, norepinephrine is released by sympathetic neurons at small swellings on minute end-branches, or *varicosities*, into the local myocyte environment (Fig. 21-11), analogous to synaptic transmission. Norepinephrine is synthesized in the varicosities from dopa and dopamine and the amino acid tyrosine. The norepinephrine thus synthesized is stored within the terminals in *storage granules* (or *vesicles*) to be released on stimulation by an adrenergic nervous impulse. Thus when central stimulation increases during excitement or exercise, an increased number of adrenergic impulses liberate an increased amount of norepinephrine from the terminals into the synaptic cleft. Most of the norepinephrine released is taken up again by the nerve terminal varicosities to reenter the storage vesicles or to be metabolized. The norepinephrine in these

FIGURE 21-11 Control of release of norepinephrine (NE) from terminal neurons. NE is released from the storage granules of terminal sympathetic neurons into the narrow synapse-like spaces near GPCRs located in the sarcolemma of the myocytes of the heart or arterial wall. In cardiomyocytes, beta-adrenergic receptors dominate, so their stimulation increases the heart rate and contractile force. In arterioles, NE has predominantly vasoconstrictive effects and acts via postsynaptic alpha₁ receptors (see Fig. 21-18). In addition, NE stimulates presynaptic alpha₂ receptors to invoke feedback inhibition of its own release, thereby modulating excess release of NE. Circulating epinephrine stimulates vascular vasodilatory beta₂ receptors but also presynaptic receptors on the nerve terminal, which promotes release of NE. Angiotensin II (A-II) is also powerfully vasoconstrictive and acts both by stimulation of NE release (presynaptic receptors, schematically shown to the left of the terminal neuron) and directly on arteriolar receptors. M_2 = muscarinic receptor, subtype two. (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L. H. Opie, © 2004.)

TABLE 21-2 Comparative Cardiovascular Effects of Alpha- and Beta-Adrenergic Receptor Stimulation

	ALPHA ₁ MEDIATED	BETA MEDIATED
Electrophysiologic effects	±	++ Conduction Pacemaker Heart rate – AP duration
Myocardial mechanics	±	++ Contractility, lusitropy Stroke volume Cardiac output
Myocardial metabolism	± Glycolysis	++ O ₂ uptake ↑ ATP
Signal systems	GPCR, can activate PKC and MAPK	GPCR, activates cAMP and PKA
Coronary arterioles	++ Constriction	+ Direct dilation +++ Indirect dilation (metabolic)
Peripheral arterioles	+++ Constriction SVR ↑ SBP ↑	+ Dilation SVR ↓ SBP ↓

AP = action potential; SBP = systolic blood pressure; SVR = systemic vascular resistance.

Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. 4th ed. Philadelphia, Lippincott, Williams & Wilkins, 2004.

synaptic clefts interacts with both alpha- and beta-adrenergic receptors on myocytes and also alpha-adrenergic receptors in arterioles (Table 21-2). The beta-adrenergic effects on the sinoatrial (SA) node and conduction system contribute to the chronotropic and dromotropic effects mentioned earlier, whereas those on myocytes are responsible mainly for the inotropic and lusitropic effects. These effects can also be modulated by coactivation of myocyte alpha-adrenergic receptors. Increased alpha-adrenergic activity causes arteriolar constriction and increased resistance, although local metabolic control of arteriolar resistance is strong in the heart and dominates coronary resistance in arterioles. Parasympathetic (vagal) innervation is strongest in the conduction system, where local release of acetylcholine (ACh) activates muscarinic receptors and tends to slow the heart rate and conduction velocity (Fig. 21-11). In these conditions the heart rate and blood pressure fall. The influence of these main effector pathways is also modulated by numerous other signaling, such as via local adenosine and nitric oxide (NO) and the powerful neuromodulator angiotensin II, which can also potentiate release of norepinephrine and vasoconstriction. Both alpha- and beta-adrenergic receptors are part of the family of seven-transmembrane domain G protein–coupled receptors (GPCRs).

Beta-Adrenergic Receptor Subtypes

Cardiac beta-adrenergic receptors are chiefly the beta₁ subtype, whereas most noncardiac receptors are beta₂. Beta₂ receptors constitute approximately 20% of the total beta receptor population in the left ventricle. Whereas beta₁ receptors are linked to the stimulatory G protein G_s, a component of the G protein–adenylyl cyclase system, beta₂ receptors are linked to both G_s and the inhibitory protein G_i, so their signaling pathway bifurcates at the very first postreceptor step.⁴ In humans, the positive inotropic response to beta₂ stimulation by salbutamol occurs, at least in part, through beta₂ receptors on the terminal neurons of cardiac sympathetic nerves, thereby releasing norepinephrine, which in turn exerts dominant beta₁ effects.⁴ Indirect evidence suggests that the G_i path is relatively augmented in heart

failure whereas the strength of the G_s path is lessened because of uncoupling of G_s from the beta₂ receptor (see Chapter 22). There also appear to be a small number of beta₃-adrenergic receptors in cardiac myocytes that seem to produce more G_i-mediated negative inotropic signaling, mediated in part by NO, but this pathway is not well understood. The beta-adrenergic receptor site is highly stereospecific, the best fit among catecholamines being achieved with the synthetic agent isoproterenol rather than with the naturally occurring catecholamines norepinephrine and epinephrine. In the case of beta₁ receptors, the order of agonist activity is isoproterenol > epinephrine = norepinephrine, whereas in the case of beta₂ receptors, the order is isoproterenol > epinephrine > norepinephrine. Human beta₁ and beta₂ receptors have both been cloned and studied extensively.⁴ The transmembrane domains are the site of agonist and antagonist binding, whereas the cytoplasmic domains interact with G proteins.

Alpha-Adrenergic Receptor Subtypes

There are two types of alpha-adrenergic receptors (alpha₁ and alpha₂). Those on the sarcolemma of vascular smooth muscle are vasoconstrictor alpha₁ receptors, whereas those situated on the terminal varicosities are alpha₂-adrenergic receptors that feed back (Fig. 21-11) to inhibit release of norepinephrine. Pharmacologically, an alpha₂-adrenergic receptor mediates a response in which the effects resemble those of the pharmacologic agent phenylephrine. Among catecholamines, the relative potencies of alpha₁-agonists are norepinephrine > epinephrine > isoproterenol. Physiologically, it is norepinephrine liberated from nerve terminals that is the chief stimulus to vascular alpha₁-adrenergic activity. Both alpha₁ and alpha₂ receptors are also found in cardiac myocytes, where their activation can fine-tune Ca²⁺ transients, ionic currents, and myofilament properties acutely, but they are also known to be important modulators of cardiac remodeling (in both adaptive and maladaptive contexts).³⁰

G proteins

The Stimulatory G Protein G_s

G proteins are a superfamily of proteins that bind guanine triphosphate (GTP) and other guanine nucleotides. G proteins are crucial in carrying the signal onward from the agonist and its receptor to the activity of the membrane-bound enzyme system that produces the second messenger cAMP (Figs. 21-12 and 21-13).⁴ Thus the combination of the beta receptor, G protein complex, and adenylyl cyclase is the crux of beta-adrenergic signaling. The G protein itself is a heterotrimer composed of G_α, G_β, and G_γ, which on receptor stimulation splits into the alpha subunit that is bound to GTP and the beta-gamma subunit. Either of these subunits may regulate different effectors such as adenylyl cyclase, phospholipase C, and ion channels. The activity of adenylyl cyclase is controlled by two different G protein complexes, namely, G_s, which stimulates, and G_i, which inhibits. The alpha subunit of G_s (α_s) combines with GTP and then separates from the other two subunits to enhance the activity of adenylyl cyclase. The beta and gamma subunits (beta-gamma) appear to be linked structurally and functionally.

The Inhibitory G Protein G_i

In contrast, a second trimeric GTP-binding protein, G_i, is responsible for inhibition of adenylyl cyclase.⁴ During stimulation of muscarinic and some beta₂-adrenergic receptors, GTP binds to the inhibitory alpha subunit α_i. The latter then dissociates from the other two components of the G protein complex, which are, as in the case of G_s, the combined beta-gamma subunits. The beta-gamma subunits act as follows. By stimulating the enzyme guanosine triphosphatase (GTPase), they break down the active α_s subunit (α_s-GTP) such that less activation of adenylyl cyclase occurs in response to alpha stimulation. Furthermore, the beta-gamma subunit activates the K_{ACh} channel, which in turn can inhibit the SA node and thereby contribute to the bradycardic effect of cholinergic stimulation. The α_i subunit may also activate another potassium channel (K_{ATP}) that stabilizes the diastolic potential. The major physiologic stimulus for G_i is

thought to be vagal muscarinic receptor stimulation (although β_2 -adrenergic receptors may contribute as well). In addition, adenosine, by interaction with A_1 receptors, couples to G_i to inhibit contraction and the heart rate. The adenosine A_2 receptor paradoxically increases cAMP. The latter effect, only of ancillary significance in the myocardium, is of major importance in vascular smooth muscle, where it induces vasorelaxation. Pathologically, G_i is increased in experimental postinfarct heart failure⁴ and in donor hearts before cardiac transplantation.⁴

FIGURE 21-12 Interaction between the sympathetic and parasympathetic systems could best be explained by countervailing influences on the second messenger cAMP mediated respectively by G_s and G_i . In response to muscarinic receptor, subtype 2 (M_2) stimulation, note the formation of G_i , with inhibitory effects on the formation of cAMP. AC = adenylate cyclase; ACh = acetylcholine; E = epinephrine; NE = norepinephrine; P = phosphate group. (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004.)

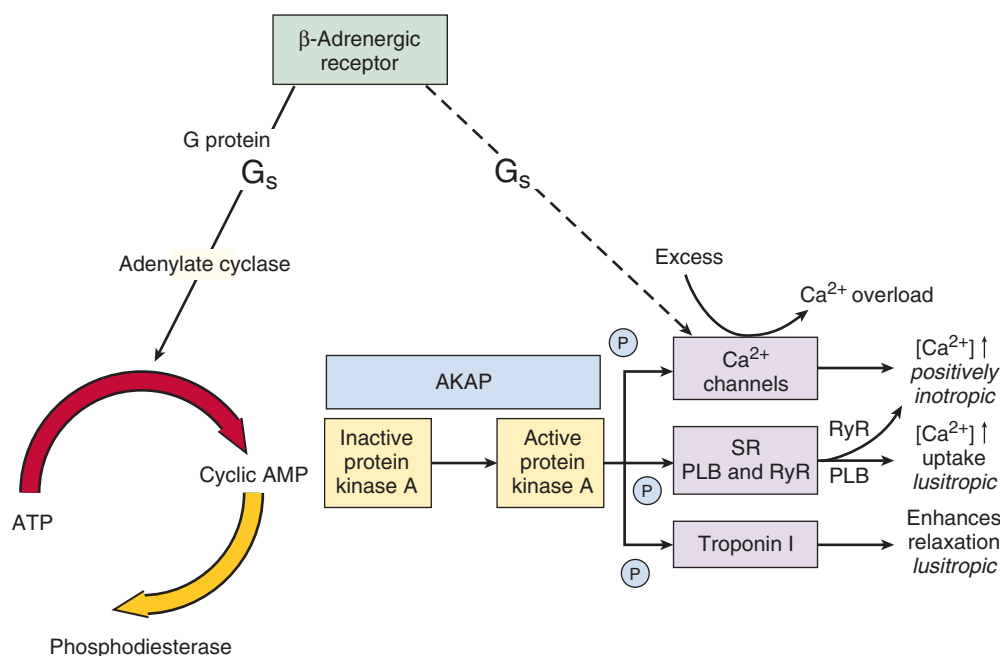

FIGURE 21-13 Key role of PKA in the beta-adrenergic response. Major intracellular effects of beta-agonist catecholamines are via the formation of cAMP, which increases the activity of PKA. PKA is localized by scaffolding proteins, AKAPs, where PKA phosphorylates various proteins concerned with contraction and relaxation. For inotropic and lusitropic mechanisms see Figure 21-14. (From Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004.)

A Third G Protein, G_q

This protein links a group of heptahelical (*hepta* = seven) myocardial receptors, including the α -adrenergic receptor and those for angiotensin II and endothelin-1, to another membrane-associated enzyme, phospholipase C, and thence to PKC (see later). G_q has at least four isoforms, two of which have been found in the heart. This G protein, unlike G_i , is not susceptible to inhibition by pertussis toxin. Overexpression of G_q in mice induces a dilated cardiomyopathy,⁴ which is of interest because angiotensin II and endothelin, which act through G_q , are overactive in human heart failure. Conversely, when the activity of G_q is genetically inhibited, the hypertrophic response to pressure overload is attenuated, wall stress increases, but cardiac function is relatively well maintained.

Cyclic Adenosine Monophosphate and Protein Kinase A

Adenylyl Cyclase

Adenylyl cyclase is a transmembrane enzyme (also sometimes called adenylylase or adenylyl cyclase) that exists in many different isoforms that respond to input from G proteins. When stimulated by G_s , adenylyl cyclase produces the second messenger cAMP, which then acts through a further series of intracellular signals and importantly the third messenger PKA to mediate the chronotropic, inotropic, lusitropic, and dromotropic effects of beta-adrenergic agonists. In contrast, cholinergic stimulation exerts inhibitory influences, largely on the heart rate, but also on contraction, and acts at least in part by decreasing the rate of formation of cAMP.

Adenylyl cyclase⁴ is the only enzyme system that produces cAMP, and it requires just low concentrations of ATP and Mg^{2+} as substrate. Surprisingly, its molecular structure somewhat resembles that of certain channel proteins, such as Ca^{2+} channels. Most of the protein is located on the cytoplasmic side, the site of interaction with the G protein. Another nucleotide, cyclic guanosine monophosphate (cGMP), acts as a second messenger for

some aspects of vagal activity and is a second messenger involved in NO signaling. cAMP has very rapid turnover as a result of a constant dynamic balance between its formation by adenylyl cyclase and conversion to AMP by another enzyme, phosphodiesterase (PDE). In general, directional changes in the tissue content of cAMP can be related to directional changes in cardiac contractile activity. For example, beta-adrenergic stimulation increases both, whereas beta blockade inhibits the increases induced by beta-agonists. *Forskolin*, a direct stimulator of adenylyl cyclase, increases cAMP and contractile activity. Adenosine, acting through A_1 receptors, inhibits adenylyl cyclase, decreases cAMP, and lessens contractile activity. A number of hormones or peptides can couple to myocardial adenylyl cyclase independently of the beta-adrenergic receptor. These are glucagon, thyroid hormone, prostacyclin, and calcitonin gene-related peptide.

Protein Kinase A

It is now clear that most of the effects of cAMP are adequately explained

by cAMP-dependent activation of PKA, a process that phosphorylates various key proteins.^{4,31} **Phosphorylation** is the donation of a phosphate group to the enzyme concerned; it acts as a fundamental metabolic switch that can extensively amplify the signal. Each PKA complex is composed of two regulatory (R) and catalytic (C) subunits. When cAMP interacts with the inactive protein kinase, it binds to the R subunit to liberate the C subunit:

The catalytic subunits can then catalyze transfer of the terminal phosphate of ATP to serine and threonine residues of the protein substrates, which leads to phosphorylation and modification of the properties of the proteins concerned and thereby promotes further key reactions. PKA occurs in two isoforms, but PKA-II predominates in cardiac cells. PKA is typically anchored near its target sites by *A-kinase anchoring proteins* (AKAPs) at specific organelles such as the SR and ion channels, which explains the phenomenon of cAMP compartmentation⁴ because anchored PKA requires focal elevation of cAMP even at an unchanged cytosolic concentration. Indeed, there is good evidence that beta-adrenergic receptors, G proteins, adenylyl cyclase, PKA, AKAP, PDE, and phosphatases can all complex on targets such as the L-type Ca channel and RyR2 to facilitate local PKA-dependent signaling (Fig. 21-13).^{14,32,33}

Beta₁-Adrenergic and Protein Kinase A Signaling in Ventricular Myocytes

The sequence of events for PKA activation is as follows (Fig. 21-14).⁴ Catecholamine stimulation → beta receptor → molecular changes → binding of GTP to the α_s subunit of G protein → GTP- α_s subunit stimulating adenylyl cyclase → formation of cAMP from ATP → activation of cAMP-dependent PKA, locally bound by an AKAP → phosphorylation of the target proteins. The L-type Ca^{2+} channel is rapidly phosphorylated by this cascade, which results in both a large increase in the amount of peak I_{Ca} and a shift in the activation voltage to more negative potentials. This increases the amount of Ca^{2+} that enters the cell at each beat and also enhances excitability (especially in pacemaker cells). In addition, the higher I_{Ca} triggers more SR Ca^{2+} release, but the higher peak I_{Ca} and SR Ca^{2+} release also enhances Ca-dependent inactivation of I_{Ca} , which limits the total amount of Ca^{2+} entry during the action potential. This contributes to an increased Ca^{2+} transient amplitude, the inotropic effect, and also the chronotropic and dromotropic effects of PKA.

The other major contributor to the inotropic effect of PKA in the heart is phosphorylation of the small single-transmembrane-spanning protein PLB. PLB associates with SERCA2 and at baseline inhibits the Ca^{2+} pump by reducing its affinity for Ca^{2+} . On phosphorylation of PLB by PKA (or CaMKII) the inhibitory effect is relieved and the Ca^{2+} pumping function is greatly enhanced. This allows more Ca^{2+} to be accumulated inside the SR during the cardiac cycle, which enhances the amount that can then be released. The faster rate of SR Ca^{2+} uptake is also the major factor in accelerating relaxation (the lusitropic effect of PKA). This occurs because twitch $[\text{Ca}^{2+}]$ decline is faster, which allows faster dissociation of Ca^{2+} from the myofilaments.

Phosphorylation of troponin I by PKA also contributes to the enhanced lusitropic effect of beta-adrenergic agonists (see Fig. 21-13). PKA-dependent troponin I phosphorylation reduces myofilament sensitivity for Ca, which is intrinsically negatively inotropic, but has the benefit of faster dissociation of Ca^{2+} from myofilaments, which hastens relaxation and diastolic filling. In addition, myosin-binding protein C is also a target for PKA, and its phosphorylation appears to be responsible for accelerating the cross-bridge turnover rate. This effect is likely to largely offset the negative inotropic effect of troponin I phosphorylation and may also hasten the rate of sarcomere

FIGURE 21-14 Signal systems involved in the positive inotropic and lusitropic (enhanced relaxation) effects of beta-adrenergic stimulation. When beta-adrenergic agonists bind beta receptors, a series of G protein-mediated changes (see Fig. 21-12) lead to the activation of adenylyl cyclase and the formation of cAMP. The latter acts via PKA to stimulate metabolism (on the left) and to phosphorylate Ca^{2+} handling proteins. The result is an enhanced opening probability of Ca^{2+} channels, thereby increasing the inward movement of Ca^{2+} through the sarcolemma (SL). This activates more release of Ca^{2+} from the SR (see Fig. 21-7) to increase $[\text{Ca}^{2+}]$, and activate troponin C. Ca^{2+} also increases the rate of breakdown of ATP to ADP and P_i . Enhanced myosin ATPase activity explains the increased rate of contraction, with increased activation of troponin C explaining the increased peak force development. The increased rate of relaxation is explained in that PKA also phosphorylates PLB on the SR membrane, which controls the Ca^{2+} affinity of SR Ca^{2+} uptake (see Fig. 21-10). The latter effect contributes to enhanced relaxation (lusitropic effect). P = phosphorylation. (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L. H. Opie, © 2004.)

shortening at a given $[\text{Ca}^{2+}]$ and mechanical load, which could enhance stroke volume.

PKA also phosphorylates the RyR; however, the impact of this effect is somewhat controversial.³⁴ One group has suggested that this displaces the immunophilin FKBP-12.6 associated with RyR2, thereby activating RyR openings, and that this is an important part of the beta-adrenergic inotropy and cardiac dysfunction in heart failure.³⁵ However, this idea has been strongly challenged by extensive mechanistic experimental data and theoretical arguments from numerous groups around the world.³⁴ Even though the effects of PKA on the cardiac RyR may enhance the rate of RyR activation during excitation-contraction coupling, it does not seem to increase the amount released (for a given I_{Ca} trigger and SR Ca^{2+} load),³⁶ nor does it directly enhance the likelihood of spontaneous SR Ca^{2+} release events.³⁷ Moreover, even when the RyR is sensitized, it causes enhanced SR Ca^{2+} release only for several beats, which then drives greater efflux of Ca^{2+} from the cell (via NCX) and reduces the SR Ca^{2+} content such that it cannot explain the enhanced Ca^{2+} transients during beta-adrenergic activation.³⁸

PKA also phosphorylates PLM, a small PLB-like protein that regulates $\text{Na}^+\text{,K}^+\text{-ATPase}$.²⁹ PLM functions in an analogous manner to PKA-dependent phosphorylation of PLB on SERCA function. That

is, at baseline PLM inhibits Na^+, K^+ -ATPase activity by reducing Na^+ affinity, but on phosphorylation by PKA (or PKC), the inhibitory effect is relieved, which increases Na^+, K^+ -ATPase function. This is actually a sensible integral part of the fight-or-flight response in that the increase in heart rate incurs more frequent I_{Na} pulses and Ca^{2+} influx (via I_{Ca}), and Na influx via NCX (which must balance that in the steady state) would result in a major increase in $[\text{Na}^+]_i$. This Na^+, K^+ -ATPase activation limits the rise in $[\text{Na}^+]_i$ during sympathetic activation and thus allows NCX to remain functional in removing Ca^{2+} from the myocyte. So the increase in Na^+, K^+ -ATPase function is somewhat negatively inotropic (by limiting $[\text{Na}^+]_i$), opposite the effect mediated by inhibition of Na^+, K^+ -ATPase by digitalis cardiac glycosides. Notably, digitalis toxicity is associated with cellular Ca^{2+} overload and arrhythmogenesis. Consequently, Na^+, K^+ -ATPase stimulation may limit these arrhythmogenic consequences associated with higher Ca^{2+} loading.

Beta-Adrenergic Receptor Desensitization

There is a potent and rapid feedback mechanism whereby the degree of postreceptor response to a given degree of beta-adrenergic receptor stimulation can be muted so that the signal can be turned off (Fig. 21-15).⁴ Physiologically, this mechanism of beta-adrenergic receptor *desensitization* occurs within minutes. Sustained beta-agonist stimulation induces the activity of a G protein-coupled receptor kinase (GRK2) called beta-adrenergic receptor kinase 1 (βARK1); βARK1 phosphorylates a site on the carboxyl-terminal of the beta-adrenergic receptor, which by itself does not switch off signaling. However, βARK activity increases beta receptor affinity for another protein family, the *arrestins*, which uncouple receptor signaling. Beta-arrestin is a scaffolding and signaling protein that links to one of the cytoplasmic loops of the beta-adrenergic receptor⁴ and lessens activation of adenylyl cyclase, thereby inhibiting receptor function. Furthermore, beta-arrestin can switch agonist coupling from G_s to G_i and also lead to internalization of the beta-adrenergic receptor.⁴ Resensitization of the receptor occurs if the phosphate group is split off by a phosphatase, and the receptor may then more readily be linked to G_s (or by recycling of the internalized receptor). Beta-arrestin signaling can also evoke an alternative counterbalancing protective path by

activating the epidermal growth factor receptor (EGFR), which leads to the protective extracellular signal-related kinase (ERK)/MAPK pathway (Fig. 21-15).³⁹⁻⁴¹ Although the GRK2-arrestin effects are best described for the β_2 receptor, they also occur with the β_1 receptor.⁴ Prolonged beta receptor stimulation, as in hyperadrenergic conditions, is linked to adverse end results in that it both impairs contractile function and enhances adverse signaling. As discussed in Chapter 22, this mechanism also plays a role in long-term desensitization of the beta-adrenergic receptor as occurs in chronic heart failure.⁴² Conversely, transgenic mice with GRK2 overexpression are protected from heart failure.⁴² Of note, the desensitization process is reversible, as occurs during experimental cardiac resynchronization therapy, when the specific suppressors of G_i (see G_i in Fig. 21-12) are much increased in activity so that beta-adrenergic signaling becomes more normal.⁴³

Calcium-Calmodulin-Dependent Kinase II

CaMKII is a serine/threonine-specific protein kinase that is regulated by the Ca^{2+} /CaM complex. CaMKII is involved in many signaling cascades in the heart, and several of the key proteins that are phosphorylated by PKA are also phosphorylated by CaMKII (typically at different amino acids). Moreover, there is good evidence that CaMKII is activated during beta-adrenergic stimulation (see Fig. 21-9).²⁰ Thus CaMKII signaling is often coactivated with PKA and can synergize at downstream targets.²⁰ CaMKII activates L-type Ca^{2+} channels (I_{Ca} facilitation), which results in increased peak I_{Ca} and also slows down inactivation, thereby boosting total Ca^{2+} influx via I_{Ca} . CaMKII also phosphorylates PLB at Thr17 (versus at Ser16 by PKA) and, via the same disinhibitory mechanism (as for PKA), can enhance SR Ca^{2+} uptake. However, the CaMKII effects on I_{Ca} and SERCA/PLB are smaller than the effects of PKA activation, so PKA is probably dominant physiologically at these targets. CaMKII can also phosphorylate RyR2 at Ser2814, close to a recognized PKA target site (2808). In contrast to the PKA story above, it is more universally agreed that CaMKII strongly activates the RyR and that this effect may be important in causing a diastolic SR Ca^{2+} leak, which can both reduce

the SR Ca^{2+} content and contribute to triggered arrhythmias.^{19,20,34} CaMKII can also phosphorylate cardiac Na^+ and K^+ channels and lead to arrhythmogenic consequences.^{19,20} CaMKII-dependent activation of the late Na^+ current may also lead to elevated intracellular $[\text{Na}^+]$ and $[\text{Ca}^{2+}]$, which can create Ca^{2+} overload and triggered arrhythmias. Myofilament proteins are also targets for CaMKII (e.g., myosin-binding protein C),³⁹ but the relative functional importance of this effect is not yet fully resolved. The chronic activation of CaMKII in pathologic states such as heart failure makes these pathways important to keep in mind.

CHOLINERGIC AND NITRIC OXIDE SIGNALING

Cholinergic Signaling

Parasympathetic stimulation reduces the heart rate and is negatively inotropic. As in adrenergic signaling, there is an extracellular messenger (ACh), a GPCR (the cholinergic muscarinic receptor), and a sarcolemmal signaling system (G protein system, specifically G_i). The myocardial *muscarinic receptor* (M_2) is a GPCR associated with the activity of vagal nerve

FIGURE 21-15 Mechanisms of beta-adrenergic receptor desensitization and internalization. Note the links between the internalized receptor complex with growth stimulation via MAPK. (Modified from Hein L, Koblik BK: Adrenergic receptors. From molecular structures to in vivo function. Trends Cardiovasc Med 7:137, 1997.)

endings. Receptor stimulation produces a negative chronotropic response that is inhibited by atropine. NO, also formed by β_3 signaling,^{43,44} facilitates cholinergic signaling at two levels, the nerve terminal and the activity of the enzyme system that produces the second messenger cGMP. *Neuregulins* are growth factors that maintain the activity of the muscarinic receptor, thereby indirectly helping balance the normal parasympathetic modulation of excess beta-adrenergic stimulation.^{45,46}

Muscarinic G_i activation also inhibits adenylyl cyclase, which functionally integrates the input from activating G_s (e.g., from β_1 -adrenergic and other receptors) and the inhibitory effects of G_i (from M_2 muscarinic and other receptors). As a consequence, vagal stimulation also reduces the resultant [cAMP] being produced by the ambient sympathetic tone and hence its impact on the heart rate (see above). The net effect is slowing of the heart rate. Vagal activity has less strong effects on atrial or ventricular myocyte electrophysiology, Ca^{2+} transients, or contractility than it does on conduction system cells, in part because of the lower density of innervation at myocytes but also because of the intrinsic properties of the cells (e.g., lacking major pacemaker function). Nevertheless, vagal activation can shorten the action potential duration in the atria and, to a lesser degree, that in the ventricles (primarily by $I_{K(ACh)}$ activation). Similarly, vagal stimulation can cause antiadrenergic effects in myocytes by effects on adenylyl cyclase, thereby limiting cAMP levels and the consequent downstream effects associated with a physiologic level of sympathetic tone.

Vagal innervation in the heart is highest in the SA and atrioventricular (AV) nodes, with lower density in atrial myocardium and the lowest density in ventricular myocardium. Activation of M_2 muscarinic receptors results in activation of the coupled G_i and consequent activation of the ACh-activated K^+ current ($I_{K(ACh)}$), which is thought to be due to tetramers that include the inward rectifier K^+ channel protomers Kir3.1 and Kir3.4. This increased K^+ conductance causes more negative diastolic potential in pacemaker cells and also hinders the rate of diastolic depolarization (in the same way that I_{K1} stabilizes the diastolic potential of atrial and ventricular myocytes). These factors slow the SA node pacemaker firing rate down and hence the heart rate.

Cyclic Guanosine Monophosphate Signaling in the Heart

The second messenger cGMP typically has negative inotropic effects in the heart, in contrast to its cyclic nucleotide cousin cAMP. cGMP is produced from GTP in cardiac myocytes mainly by soluble and particulate guanylyl cyclase, which are activated downstream of NO and natriuretic peptide receptor activation, respectively (Fig. 21-16), and possibly by cholinergic effects. Local subcellular regions in which NO and cGMP signaling takes place are also likely to exist.³² Of note, cell-permeable analogues of cGMP have antiadrenergic effects. When the cGMP concentration is elevated locally, it can stimulate protein kinase G (PKG), which results in inhibitory cardiac effects such as a decreased heart rate and negative inotropic response. These effects are largely achieved by modulation of Ca^{2+} entry through L-type Ca^{2+} channels and through alteration of internal Ca^{2+} cycling.^{46,47} PKG has also been suggested to be a critical suppressor of pathophysiologic hypertrophy.⁴⁸

cGMP is broken down by PDE, and seven PDE isoforms are expressed in the heart, some of which break down both cAMP and cGMP (PDE1 to PDE3) whereas PDE4 is cAMP specific and PDE5 is cGMP specific.⁴⁷ PDE5 has achieved prominence as result of its inhibition by sildenafil and related compounds that all enhance penile vasodilation. Emerging data show wider therapeutic potential. Thus sildenafil, by accumulation of cGMP, combats the harmful excessive adrenergic stimulation of contractile function. Furthermore, via cGMP sildenafil can inhibit excess left ventricular (LV) growth in response to aortic constriction.⁴⁹ Conversely, in human cardiac hypertrophy and heart failure, PDE5 is more highly expressed, which may exacerbate adverse remodeling. The key target of cGMP, PKG, like its counterpart PKA, colocalizes with its targets to control

FIGURE 21-16 Proposed role of NO in stimulating soluble guanylyl cyclase to form cGMP and thereby cause vasodilation and negative inotropic effects. In the myocardium there is inhibition of maladaptive growth. Antianginal nitrates also cause coronary vasodilation by this mechanism. Natriuretic peptides and their receptors (NPR) increase myocardial cGMP. LVH = left ventricular hypertrophy; Mito = mitochondrial. (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L. H. Opie, © 2004.)

substrate phosphorylation.⁵⁰ The anchoring protein for PKG may be the same AKAP as for PKA, thus allowing tight subcellular colocalization and regulation of the counterpoised activities of cAMP and cGMP and hence of their respective upstream signaling cascades.⁴⁷

Nitric Oxide

NO, the focus of the Nobel Prize Award for 1998, is a unique messenger in that it is formed in so many tissues, is a gas, and is a physiologic free radical (see Chapter 22). NO is generated in the heart by one of three isoenzymes.⁴⁶ All three isoforms are present in the heart, including NOS1 (nNOS, or neuronal NOS), NOS2 (iNOS, or inducible NOS), and NOS3 (eNOS, or endothelial NOS).^{51,52} NO signaling is reviewed in Chapter 22 and Figure e22-2.

Reactive Oxygen Species As Signaling Molecules

As discussed in Chapter 22, ROSs are a normal byproduct of aerobic metabolism. Potential sources for ROSs in the heart include the mitochondria, xanthine oxidase, and the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (see Fig. 22-5). ROSs can modulate the activity of a variety of intracellular proteins and signaling pathways, including essential proteins involved in myocardial excitation-contraction coupling, such as ion channels, SR Ca^{2+} release channels, and myofilament proteins, as well as signaling pathways that are coupled to myocyte growth^{53,54} (see Chapter 22 for further discussion of ROSs).

CONTRACTILE PERFORMANCE OF INTACT HEARTS

Myocardial mechanical performance has three main determinants: the loading conditions (preload or Frank-Starling mechanism and afterload), the contractile state (inotropy or contractility and lusitropy), and the heart rate. This section describes the cardiac cycle and then the determinants of LV function.

The Cardiac Cycle

The cardiac cycle, fully assembled by Lewis⁵⁵ but first conceived by Wiggers,⁵⁶ yields important information on the temporal sequence of events in the cardiac cycle (Fig. 21-17). The three basic events with respect to the left ventricle are (1) LV contraction, (2) LV relaxation, and (3) LV filling (Table 21-3). Similar mechanical events occur in the right ventricle, but the focus here will be on the left ventricle.

Left Ventricular Contraction

LV pressure starts to build up when Ca^{2+} arrives at the contractile proteins and triggers actin-myosin interaction.⁴ This occurs shortly after upstroke of the ventricular action potential, where the advance

of the wave of depolarization is indicated by the QRS complex of the electrocardiogram (Fig. 21-17). As soon as LV pressure builds up and exceeds that in the left atrium (normally 10 to 15 mm Hg), the mitral valve closes (with minor inertial delay, ≤ 20 milliseconds), and that causes M_1 , the mitral component of the first sound. Changes in right ventricular (RV) pressure are usually slightly delayed because of electrical conduction such that closure of the tricuspid valve causes T_1 , which is the second component of the first heart sound. During the phase of contraction after mitral closure and before aortic opening, LV volume is fixed (*isovolumic contraction*) because both the aortic and mitral valves are shut. As more and more myofibers are activated to contract, LV pressure development proceeds. When

The Lewis or Wiggers Cycle

FIGURE 21-17 Mechanical events in the cardiac cycle, first assembled by Lewis in 1920⁵⁵ but first conceived by Wiggers in 1915.⁵⁶ Note that mitral valve closure occurs *after* the crossover point of atrial and ventricular pressure at the start of systole. The visual phases of the ventricular cycle in the **bottom panel** are modified from Shepherd and Vanhoutte (Shepherd JT, Vanhoutte PM: *The Human Cardiovascular System*. New York, Raven Press, 1979, p 68). For an explanation of phases a to g, see Table 21-3. ECG = electrocardiogram; JVP = jugular venous pressure; M_1 = mitral component of the first sound at the time of mitral valve closure; T_1 = tricuspid valve closure, second component of the first heart sound; AO = aortic valve opening, normally inaudible; A_2 = aortic valve closure, aortic component of the second sound; MO = mitral valve opening, may be audible in mitral stenosis as the opening snap; P_2 = pulmonary component of the second sound, pulmonary valve closure; S_3 = third heart sound; S_4 = fourth heart sound; a = wave produced by right atrial contraction; c = carotid wave artifact during the rapid LV ejection phase; v = venous return wave, which causes pressure to rise with the tricuspid valve closed. The cycle length was 800 milliseconds for 75 beats/min. (From Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004.)

TABLE 21-3 The Cardiac Cycle

LV Contraction
Isovolumic contraction (b)
Maximal ejection (c)
LV Relaxation
Start of relaxation and reduced ejection (d)
Isovolumic relaxation (e)
LV filling: rapid phase (f)
Slow LV filling (diastasis) (g)
Atrial systole or kick (a)

The letters a to g refer to the phases of the cardiac cycle shown in Wiggers' diagram (see Fig. 21-17). These letters are arbitrarily allocated so that atrial systole (a) coincides with the A wave and (c) with the C wave of jugular venous pressure.

LV pressure exceeds aortic pressure, the aortic valve opens, usually a clinically silent event. Opening of the aortic valve is followed by the phase of *rapid ejection*. The rate of ejection is determined not only by the pressure gradient across the aortic valve but also by the elastic properties of the aorta and the arterial tree, which undergoes systolic expansion. LV pressure rises to a peak and then starts to fall.

Left Ventricular Relaxation

As myocyte $[Ca^{2+}]_i$ starts to decline because of SR Ca^{2+} uptake, Ca^{2+} dissociates from troponin C, thereby preventing further cross-bridge formation.⁴ As this state of relaxation progresses, the rate of LV ejection of blood into the aorta falls (*phase of reduced ejection*). During this phase, blood flow from the left ventricle to the aorta rapidly diminishes but is maintained by aortic recoil—the Windkessel effect.⁴ When the pressure in the aorta significantly exceeds the falling LV pressure, the aortic valve closes, which creates the first component of the second sound, A_2 (the second component, P_2 , results from closure of the pulmonary valve as pulmonary artery pressure exceeds RV pressure). Thereafter, the ventricle continues to relax. Because the mitral valve is still closed during this phase after aortic closure, LV volume cannot change (*isovolumic relaxation*). When LV pressure falls to below that in the left atrium, the mitral valve opens (normally silent) and the filling phase of the cardiac cycle restarts (Fig. 21-17).

Left Ventricular Filling Phases

As LV pressure drops below that in the left atrium, just after mitral valve opening, the *phase of rapid or early filling* occurs and accounts for most of the ventricular filling.⁴ Active diastolic relaxation of the ventricle may also contribute to early filling. Such rapid filling may cause the physiologic third heart sound (S_3), particularly in individuals with a hyperkinetic circulation.⁴ As pressures in the atrium and ventricle equalize, LV filling virtually stops (*diastasis*, separation). Renewed filling requires that atrial pressure exceed LV pressure. This is achieved by *atrial systole* (or the *left atrial kick*), which is especially important at a high heart rate, as during exercise, or when the left ventricle fails to relax normally as in LV hypertrophy.⁴

Definitions of Systole and Diastole

In Greek, *systole* means “contraction” and *diastole* means “to send apart.”⁴ The start of systole can be regarded either as (1) the beginning of isovolumic contraction when LV pressure exceeds atrial pressure or as (2) mitral valve closure (M_1), which are almost simultaneous. *Physiologic systole* lasts from the start of isovolumic contraction (when LV pressure crosses over atrial pressure, Fig. 21-17) to the peak of the ejection phase, so physiologic diastole commences as LV pressure starts to fall (Table 21-3). This concept fits well with the standard pressure-volume curve. *Physiologic diastole* commences as Ca^{2+} is taken back into the SR, so myocyte relaxation dominates over contraction, and LV pressure starts to fall as shown on the pressure-volume curve. In contrast, *cardiologic systole* is demarcated by the interval between the first and second heart sounds and lasts from the first heart sound (M_1) to closure of the aortic valve (A_2). The

remainder of the cardiac cycle automatically becomes *cardiologic diastole*. Thus cardiologic systole, demarcated by heart sounds rather than by physiologic events, starts fractionally later than physiologic systole, ends significantly later, but is more closely aligned with ejection time. For the cardiologist, *protodiastole* is the early phase of rapid filling, the time when the third heart sound (S_3) can be heard. This sound probably reflects ventricular wall vibrations during rapid filling and becomes audible with an increase in LV diastolic pressure or wall stiffness or the rate of filling.

Contractility Versus Loading Conditions

Contractility

Contractility, or the inotropic state, is the inherent capacity of the myocardium to contract independently of changes in preload or afterload (and these two terms are largely synonymous).⁴ These are key terms in our cardiologic language. At the molecular level, an increased inotropic state is usually explained by either enhanced transients or enhanced myofilament Ca^{2+} sensitivity and typically means a greater rate of contraction to reach a greater peak force. Frequently, increased contractile function is associated with enhanced rates of relaxation, or a lusitropic effect (e.g., as during beta-adrenergic activation). Contractile function is an important regulator of myocardial oxygen uptake. Factors that increase contractility include exercise, adrenergic stimulation, digitalis, and other inotropic agents.

Preload and Afterload

It is important to stress that any change in contractility should be independent of the loading conditions.⁴ *Preload* is the load present before contraction has started, typically using end-diastolic pressure or volume (EDP or EDV) as an index. *Afterload* is the load that the left ventricle does work against during ejection (with aortic pressure being the simplest index). When preload increases, the left ventricle distends during diastole, and stroke volume rises according to Starling's law (see the next section). The heart rate also increases by stimulation of atrial mechanoreceptors, which enhances the rate of discharge of the SA node. Thus cardiac output (stroke volume times heart rate) rises.

Starling's Law of the Heart

Venous Filling Pressure and Heart Volume

Starling in 1918 related venous pressure in the right atrium to heart volume in the dog heart-lung preparation.⁴ He proposed that within physiologic limits, the larger the volume of the heart, the greater the energy of its contraction and the amount of chemical change at each contraction. Starling did not, however, measure sarcomere length. He could relate only *LV volume* to cardiac output. This holds in normal, compliant hearts. One modern version of Starling's law is that stroke volume is related to EDV. LV volume can now be directly measured with two-dimensional echocardiography. Yet the value found depends on a number of simplifying assumptions such as a spherical LV shape and neglects the confounding influence of the complex LV anatomy. From an investigational point of view, real-time three-dimensional echocardiographic records can now yield both global LV volume and endocardial function.⁵⁷ In practice, however, LV volume is not often measured; instead, a variety of surrogate measures such as LVEDP or pulmonary capillary wedge pressure are used. The relationship between LVEDV and LVEDP is curvilinear, with the slope reflecting LV compliance. LV diastolic *filling pressure* (the difference between left atrial [LA] and LV diastolic pressure) is easier to measure and, in diseased, noncompliant hearts, may be taken as a surrogate for heart volume. Venous filling pressure can be measured in humans, albeit indirectly by the technique of *Swan-Ganz catheterization*, as can stroke volume. LV pressure and volume are, however, not linearly related because of variations in compliance of the myocardium. Therefore a jump from pressure to volume is required to apply the Starling concept to the hemodynamic management of those critically ill and receiving a Swan-Ganz catheter.

Frank and Isovolumic Contraction

If a larger heart volume increases the initial length of the muscle fiber, to increase stroke volume and hence cardiac output, diastolic stretch of the left ventricle (and increased sarcomere length) increases the force of contraction.⁴ Frank in 1895 had already reported that the greater the initial LV volume, the more rapid the rate of rise, the greater the peak pressure reached, and the faster the rate of relaxation (see Figure 21-6 in Opie⁵). He described both a positive *inotropic effect* (*ino*, fiber; *tropus*, move) and an increased lusitropic effect. These complementary findings of Frank and Starling are often combined into the *Frank-Starling law*. Thus when there is an increase in the strength of contraction, it can generally be categorized as either a *Frank-Starling effect* (increased sarcomere length) or an inotropic effect (altered Ca^{2+} transient or myofilament Ca^{2+} sensitivity), but of course both effects can occur simultaneously. Being able to parse effects mechanistically in this way can be of help in selecting therapeutic interventions.

Afterload

This is the systolic load on the left ventricle after it has started to eject blood.⁴ Notably, the left ventricle cannot sense what the afterload is until it reaches a pressure that allows opening of the aortic valve. In a nonfailing heart, the left ventricle can overcome any physiologic acute increase in load. Chronically, however, the left ventricle must hypertrophy to overcome sustained arterial hypertension, significant aortic stenosis, or postinfarct necrosis. In clinical practice, arterial blood pressure is often taken to be synonymous with afterload while ignoring *aortic compliance*—the extent to which the aorta can “yield” during systole. A stiff aorta, as in isolated systolic hypertension of the elderly, increases afterload.

Preload and Afterload Are Interlinked

Although the above distinctions between preload and afterload are useful, one can influence the other. According to the Frank-Starling law, increased LV volume leads to increased contractile function, which in turn increases systolic blood pressure and hence afterload. During LV ejection, sarcomere length progressively declines. This decline dynamically decreases both myofilament Ca^{2+} sensitivity and maximal force, which along with the progressive decline in $[\text{Ca}^{2+}]_i$, reduces contractile force. However, afterload also dynamically changes during ejection and declines as ejection wanes. Nonetheless, in general, preload is related to the degree to which myocardial fibers are stretched at the end of diastole, and afterload is related to the wall stress generated by these fibers during systole.

Force-Length Relationships and Ca^{2+} Transients

Acute changes in sarcomere length do not alter the Ca^{2+} transient appreciably. The favored explanation for the steep length-tension relationship of cardiac muscles is increased myofilament Ca^{2+} sensitivity as the initial sarcomere length increases.⁴ In cardiac muscle, even at 80% of the length at which maximal force is developed (L_{\max}), only 10% or less of the maximal force is developed. Thus it can be predicted that cardiac sarcomeres (and physiologic EDV) must function near L_{\max} . Rodriguez and coworkers⁵⁸ tested this prediction by relating changes in sarcomere length to changes in volume of the intact heart. By implanting small radiopaque beads in only approximately 1 cm³ of the LV free wall and using biplane cineradiography, bead motion could be tracked through the cardiac cycles with allowances made for myocardial deformation. Thus the change in sarcomere length from approximately 85% of L_{\max} to L_{\max} itself is able to effect changes in physiologic LV volume (Fig. 21-18). This estimate is remarkably close to the normal fiber shortening of 15% in the human heart in situ.⁴

Anrep Effect: Abrupt Increase in Afterload

When aortic pressure is elevated abruptly, ejection is limited and EDV tends to increase, which acutely increases force and pressure at the next beat via the Frank-Starling effect.⁴ However, there is a slower adaptation that takes seconds to minutes whereby the inotropic state of the heart increases (and Ca^{2+} transients are larger). Both phases of

this process can readily be recapitulated in isolated muscle strips from the heart. This slow force response or adaptation is referred to as the Anrep effect (based on von Anrep's 1912 paper). Extensive study has implicated stretch-induced activation of several important autocrine/paracrine myocyte signaling pathways in this slowly developing inotropic effect.⁵⁹ These include angiotensin II, endothelin-1, EGFRs, mitochondrial ROS production, activation of Na/H exchange, increased $[\text{Na}^+]_i$ and NCX-dependent Ca^{2+} loading, and enhanced Ca^{2+} transients.

Wall Stress

A more exact definition of afterload is the wall stress during LV ejection.⁴ Technically, wall stress develops when tension is applied to a cross-sectional area, and the units are force per unit area. According to Laplace's law (Fig. 21-19), wall stress = (pressure \times radius)/

FIGURE 21-18 Length sensitization of the sarcomere. In the **top panel**, sarcomere length (SL) is 1.65 μm , which provides very little development of force (f). In the **bottom panel**, at an almost maximum sarcomere length, the same Ca^{2+} transient (c) with the same peak value and overall pattern causes much greater development of force. Therefore length-induced calcium sensitization has taken place. (Modified from Backx PH, ter Keurs HEDJ: Fluorescent properties of rat cardiac trabeculae microinjected with fura-2 salt. *Am J Physiol* 264:H1098, 1993.)

FIGURE 21-19 Wall stress increases as afterload increases. The formula shown is derived from Laplace's law. The increased LV pressure in aortic stenosis is compensated for by LV wall hypertrophy, which decreases the denominator on the right side of the equation. R = radius. (From Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004.)

($2 \times$ wall thickness). This equation, although an oversimplification, emphasizes two points. First, the larger the LV size and radius, the higher the wall stress.⁴ Second, at any given radius (LV size), the greater the pressure developed by the left ventricle, the greater the wall stress. An increase in wall stress achieved by either of these two mechanisms (LV size or intraventricular pressure) will increase myocardial oxygen uptake because a greater rate of ATP use is required as greater tension develops in the myofibrils.

In cardiac hypertrophy, Laplace's law explains the effects of changes in wall thickness on wall stress (Fig. 21-19). The increased wall thickness from hypertrophy balances the increased pressure, and wall stress remains unchanged during the phase of compensatory hypertrophy.⁴ The notion that this change is compensatory and beneficial has been challenged by a mouse model in which the process of hypertrophy was genetically inhibited so that wall stress increased in response to a pressure load, yet these mice had better cardiac mechanical function than did the wild-type mice in which compensatory hypertrophy developed.⁴ Despite this "mighty mouse" challenge, it is difficult to see how a patient with significant aortic stenosis could develop the required intraventricular pressure to eject blood through the stenosed valve without the development of LV hypertrophy. Another clinically useful concept is that in congestive heart failure, the heart dilates so that the increased radius elevates wall stress. Furthermore, because ejection of blood is inadequate, the radius stays too large throughout the contractile cycle, and both end-diastolic and end-systolic wall stress is higher. The overall reduction in heart size decreases wall stress and improves LV function.⁴

Wall Stress, Preload, and Afterload

This definition brings in both the volume and the fiber length that define the radius (Fig. 21-19).⁴ *Preload* can now be defined more exactly as the wall stress at the end of diastole and therefore at the maximal resting length of the sarcomere (Fig. 21-19). Measurement of wall stress in vivo is difficult because use of the radius of the left ventricle (see the preceding sections) neglects the confounding influence of the complex LV anatomy. Surrogate preload indices include LVEDP or dimensions (the latter being the major and minor axes of the heart in a two-dimensional echocardiographic view). *Afterload*, being the load on the contracting myocardium, is also the wall stress during LV ejection. Increased afterload means that increased intraventricular pressure has to be generated first to open the aortic valve and then during the ejection phase. These increases will translate into increased myocardial wall stress, which can be measured either as an average value or at end-systole.

Peak systolic wall stress reflects the three major components of afterload, namely, peripheral resistance, arterial compliance, and peak intraventricular pressure.⁴ Decreased arterial compliance and increased afterload can be anticipated with aortic dilation, as in severe systemic hypertension or in the elderly. Generally, in clinical practice it is a sufficient approximation to use systolic blood pressure as an indirect measure of afterload (reflecting both peripheral resistance and peak intraventricular pressure), provided that neither significant aortic stenosis nor a change in arterial compliance has occurred. LV global longitudinal strain measured by velocity vector imaging echocardiography is a more sensitive index of LV mechanics than the standard LV ejection fraction as measured by echocardiography, although more difficult to measure.⁶⁰ The systolic timing of the afterload can also influence LV relaxation. In experimental and human studies, a late systolic load, as when the aorta has stiffened, is associated with impaired LV relaxation.⁶¹

Aortic impedance (= arterial input impedance) gives another accurate measure of afterload. Aortic impedance is aortic pressure divided by aortic flow at that instance, so this index of afterload varies at each stage of the contraction cycle.⁴ Factors reducing aortic flow, such as high arterial blood pressure, aortic stenosis, or loss of aortic compliance, will increase impedance and hence afterload. During systole, when the aortic valve is open, increased afterload will communicate itself to the ventricles by increasing wall stress. In LV failure, aortic impedance is augmented not only by peripheral vasoconstriction but also by decreases in aortic compliance. The problem with clinical

measurement of aortic impedance is that invasive instrumentation is required. An approximation can be found by using transthoracic echocardiography to determine aortic blood flow at, for example, the time of maximal increase in aortic flow just after aortic valve opening.

Heart Rate and Force-Frequency Relationship

Treppé or Bowditch Effect

An increased heart rate progressively enhances the force of ventricular muscle contraction, even in isolated papillary muscle preparations and isolated myocytes (Bowditch staircase phenomenon).⁴ Alternative names are the *treppé* (steps, German) phenomenon, positive inotropic effect of activation, or force-frequency relationship (Fig. 21-20A). Conversely, a decreased heart rate has a negative staircase effect. However, at a very high heart rate, force progressively decreases. These effects at the myocyte level are largely attributable to changes in Na^+ and Ca^{2+} in the myocyte. At a higher heart rate there is more Na^+ and Ca^{2+} entry per unit time and less time for the cell to extrude these ions, which results in higher $[\text{Na}^+]_i$ and cellular and SR Ca^{2+} content.² The increase in SR Ca^{2+} content increases the amount of Ca^{2+} released during the action potential, and that is the primary cause of the increase in contractility at higher heart rates. The elevation in $[\text{Na}^+]_i$ also further reduces the efficacy of NCX in extruding Ca^{2+} during the cardiac cycle, thereby leading to further gains in cellular (and SR) Ca^{2+} . A new steady-state Ca^{2+} load will be achieved

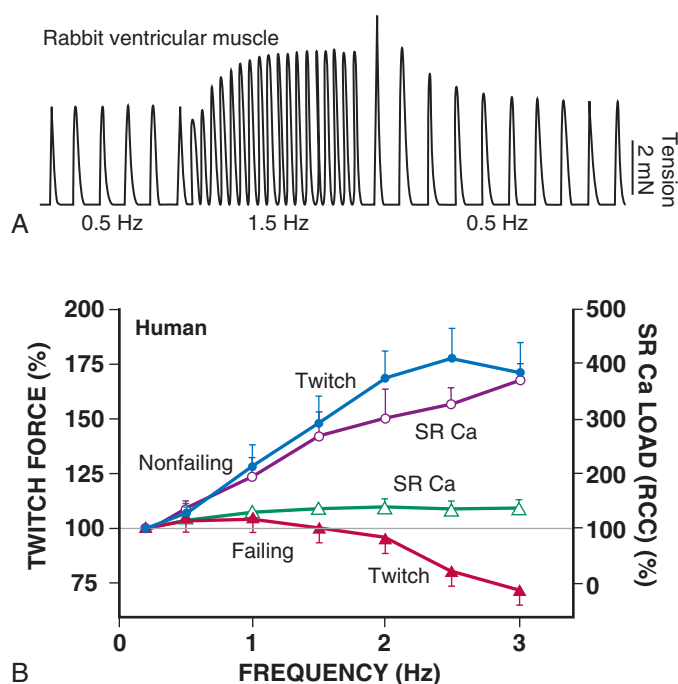

FIGURE 21-20 Heart rate dependence on contraction: Bowditch or *treppé* phenomenon. **A**, An increased stimulation rate increases the force of contraction. The tension developed by rabbit ventricular muscle is shown in mN. During the first shortened diastolic interval the first beat is smaller, an effect caused mainly by refractoriness of the SR Ca^{2+} release channel. As the 1.5-Hz stimulation approaches a steady state, the contraction is progressively increased, an effect attributable to the gain in myocyte Na^+ and Ca^{2+} and enhanced SR Ca^{2+} content. When the diastolic interval is prolonged (first beat at 0.5 Hz), the first beat is especially large because the SR Ca load is still elevated and there is more time for the RyR to recover from refractoriness. The larger Ca^{2+} transient then drives higher extrusion of Ca^{2+} from the cell as the initial 0.5-Hz steady state is eventually achieved. **B**, With an increasing heart rate, normal nonfailing ventricular muscle exhibits a progressive increase in SR Ca^{2+} content (SR Ca) and a positive force-frequency relationship that peaks at approximately 2.5 Hz. The decline at 3 Hz is due to reduced fractional SR Ca^{2+} release. In failing human ventricular muscle the SR fails to increase its Ca^{2+} content appreciably at higher heart rates; this results in a negative force-frequency relationship (which is dominated by the refractoriness but here is not compensated by increased SR Ca). SR Ca in this study was assessed by rapid-cooling contractions (RCC). (From Bers DM: *Excitation-Contraction Coupling and Cardiac Contractile Force*. Dordrecht, Netherlands, Kluwer Academic, 2001.)

when the increased Ca^{2+} transients cause Ca^{2+} extrusion via NCX to match the amount of Ca^{2+} influx at each beat (and similarly when Na^+, K^+ -ATPase extrudes the amount of Na^+ that enters per beat). This is the definition of steady state, with no net gain or loss of cellular Ca^{2+} (or Na^+) from beat to beat.

To the extent that the SR can take up this extra Ca^{2+} load at a higher heart rate, diastolic $[\text{Ca}^{2+}]_i$ and stiffness remain low. This is helped by an increase in the rate of SR Ca^{2+} uptake at a higher heart rate (known as frequency-dependent acceleration of relaxation) mediated by faster SR Ca^{2+} uptake function (although the mechanism is not fully resolved). However, if SR Ca^{2+} -ATPase and NCX are unable to remove Ca^{2+} sufficiently from the cytoplasm during the time between beats, an increase in diastolic $[\text{Ca}^{2+}]_i$ and force/stiffness will occur. Systolic function is also limited at increasing heart rates. The primary reason at physiologic heart rates is that the SR Ca^{2+} release process has refractoriness that is reminiscent of that seen with voltage-gated Na^+ and Ca^{2+} channels. Thus at higher heart rates, even when a normal action potential and Ca^{2+} current signal occur, the fraction of SR Ca^{2+} released can be reduced (Fig. 21-20B). In a sense we can think of the resulting Ca^{2+} transient and contraction at increasing heart rates as the product of the increasing SR Ca^{2+} content times the declining fractional SR Ca^{2+} release, with the former factor being dominant (especially at more moderate heart rate) but the latter being progressively limiting.

In the intact heart this scenario is complicated by alterations in filling time and consequent changes in preload. That is, at higher heart rates there will also be a reduced filling time that will limit preload, and thus a negative Frank-Starling effect will modulate the positive and negative inotropic effects above to limit the overall strength of LV contraction. In addition, higher aortic pressure at high heart rates will also increase cardiac afterload and limit the ability of the left ventricle to eject blood. Thus both fundamental myocyte and hemodynamic properties combine to influence net cardiac function at increased heart rates.

PVCs or extrasystoles can also modulate contraction in understandable ways. When a PVC occurs during the time when SR Ca^{2+} release is partially refractory and the left ventricle has not been refilled, the strength of that PVC will be very weak and may even fail to open the aortic valve. However, because the PVC had low SR Ca^{2+} release, less Ca^{2+} current inactivation and less Ca^{2+} extrusion from the cell occur and result in very much higher SR Ca^{2+} release at the next (postextrasystolic) beat following the usual compensatory pause (because of AV node refractoriness during the next sinus node beat). Similarly, the much smaller LV ejection and continued LV filling by the time that the postextrasystolic beat occurs result in greater preload and reduced afterload. These cellular and hemodynamic effects conspire to cause an extremely strong postextrasystolic contraction. This strong postextrasystolic potentiation beat is what a person can often sense as the heart “skipping a beat.”

Physiologic Force-Frequency Relationship and Optimal Heart Rate

When the heart rate increases under physiologic conditions, it is usually accompanied by sympathetic beta-adrenergic activation at myocytes throughout the heart. As discussed earlier, this will increase Ca^{2+} current influx, the rate of SR Ca^{2+} uptake, and the amount of SR Ca^{2+} released during the beat, which greatly amplifies the inotropic and lusitropic effects described earlier that are associated with alteration of the heart rate without sympathetic activation. However, the beta-adrenergic system also enhances Na^+, K^+ -ATPase activity to limit the rise in $[\text{Na}^+]_i$ that occurs at the higher heart rate, and this would temper the overall inotropic effect. Normally, peak contractile force at a fixed muscle length (isometric contraction) increases and a peak is reached at about 150 to 180 beats/min (Fig. 21-20B).^{2,4} This is the human counterpart of the treppe phenomenon. In situ, the optimal heart rate is also dependent on the hemodynamic factors above and a functioning sympathetic system, so the exact value of the heart rate when cardiac output starts to decrease rather than increase is harder to specify. Pacing rates of up to 150/min can be tolerated, whereas higher rates cannot because of the development of AV block. In

FIGURE 21-21 Major determinants of the O_2 demand of the normal heart: heart rate, wall stress, and contractile function. (Modified with permission from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004.)

contrast, during exercise, indices of LV function still increase up to a maximum heart rate of about 170/min, presumably because of enhanced contractile function and peripheral vasodilation.⁴ In patients with severe LV hypertrophy, the critical heart rate is between 100 and 130/min, with a fall-off in LV function at higher rates.

Myocardial Oxygen Uptake

Myocardial oxygen demand can be increased by the heart rate, preload, or afterload (Fig. 21-21), factors that can all precipitate myocardial ischemia in those with coronary artery disease. Oxygen uptake can also be augmented by increased contractile function, as during beta-adrenergic stimulation. Because myocardial oxygen uptake ultimately reflects the rate of mitochondrial metabolism and ATP production, any increase in ATP requirement will be reflected in increased oxygen uptake. In general, factors increasing wall stress will increase oxygen uptake. Increased afterload causes increased systolic wall stress, which requires greater oxygen uptake. Increased diastolic wall stress, resulting from increased preload, will also require more oxygen because the greater stroke volume must be ejected against the afterload. In states of enhanced contractile function, the rate of change in wall stress is increased. Thus thinking in terms of wall stress provides a comprehensive approach to the problem of myocardial oxygen uptake. Because systolic blood pressure is an important determinant of afterload, a practical index of oxygen uptake is systolic blood pressure \times heart rate, the *double product*. In addition, the metabolic component in oxygen uptake is usually small but may be prominent in certain special conditions, such as the “oxygen wastage” found during abnormally high circulating free fatty acids in hyperadrenergic conditions (e.g., severe heart failure).⁶² The concept of wall stress in relation to oxygen uptake also explains why heart size is such an important determinant of myocardial oxygen uptake (because a larger radius increases wall stress).

Work of the Heart

External work (pressure \times volume) is done by the heart, with stroke volume (or cardiac output) being the volume moved against arterial blood pressure. Volume work (associated with increased stroke

volume) requires less oxygen than pressure work does (increased pressure or heart rate), and it might be supposed that external work is not an important determinant of myocardial oxygen uptake. However, three determinants of myocardial oxygen uptake are involved: preload (because this helps determine stroke volume), afterload (in part determined by blood pressure), and heart rate, as can be seen from the following formula:

$$\text{Minute work} = \text{SBP} \times \text{SV} \times \text{HR}$$

where SBP = systolic blood pressure, SV = stroke volume, and HR = heart rate. Thus it is not surprising that heart work is related to oxygen uptake. This *pressure-work index* takes into account both the double-product (SBP \times HR) and HR \times SV (i.e., cardiac output). The *pressure-volume area* is another index of myocardial oxygen uptake but requires invasive monitoring for accurate measurements. External cardiac work can account for up to 40% of the total myocardial oxygen uptake.

Internal Work (Potential Energy)

Total oxygen consumption is related to the total work of the heart (area *abcd* in Fig. 21-22), which means that both external work (area *abce*) and the volume-pressure triangle joining the end-systolic volume-pressure point to the origin (area *cde*; marked PE).⁶³ Although this area has been called internal work, more strictly it should be called the *potential energy* that is generated within each contraction cycle but not converted to external work. Such potential energy at the end of systole (point *c*) may be likened to the potential energy of a compressed spring.

Kinetic Work

In strict terms, *power production* needs to take into account not only pressure but also kinetic components. It is the pressure work that has been discussed (product of cardiac output and peak systolic pressure). Kinetic work is the component required to move blood against the afterload. Normally, kinetic work is less than 1% of the total. In aortic stenosis, kinetic work increases sharply as the cross-sectional area of the aortic valve narrows, whereas pressure work increases as the gradient across the aortic valve rises. Noninvasive measures of peak power production are being assessed as indices of cardiac contractile function.

Efficiency of work is the relationship between the work performed and myocardial oxygen uptake. Exercise increases the efficiency of external work, an improvement that offsets any metabolic cost of the increased contractile function.⁴ Metabolically, efficiency is increased

by promotion of glucose rather than fatty acids as the major myocardial fuel. Conversely, heart failure decreases the efficiency of work, possibly by beta-adrenergic-promoted fatty acid metabolism. The subcellular basis for changes in the efficiency of work is not fully understood. Because as little as 12% to 14% of oxygen uptake may be converted to external work,⁴ it is probably the "internal work" that becomes less demanding. Internal ion fluxes (Na⁺/K⁺/Ca²⁺) account for approximately 20% to 30% of the ATP requirement of the heart, so most ATP is spent on actin-myosin interaction and much of that on the generation of heat rather than on external work. An increased initial muscle length sensitizes the contractile apparatus to Ca²⁺, thereby theoretically increasing the efficiency of contraction by diminishing the amount of Ca²⁺ flux required.

Measurements of Contractile Function

Force-Velocity Relationship and Maximum Contractile Function in Muscle Models

If contractility is truly independent of load and the heart rate, unloaded heart muscle stimulated at a fixed rate should have a maximum value of contractile function for any given magnitude of the cytosolic Ca²⁺ transient. This value, the V_{\max} of muscle contraction, is defined as the *maximal velocity of contraction* when there is no afterload to prevent maximal rates of cardiac ejection.⁴ Beta-adrenergic stimulation increases V_{\max} , and converse changes are found in failing myocardium. V_{\max} is also termed V_0 (maximum velocity at zero load). As the load increases, the velocity of shortening decreases. A limitation of this relatively simple concept is that V_{\max} cannot be measured directly but must be extrapolated from the *force-velocity relationship* to the velocity axis intercept. The other extreme condition is zero muscle shortening, with all the energy going into the development of pressure (P_0) or force (F_0). This situation is an example of *isometric shortening* (*iso* = the same; *metric* = length).

The concept of V_{\max} has been subject to much debate over many years, chiefly because of the technical difficulties in obtaining truly unloaded conditions. Braunwald and colleagues⁶⁴ used cat papillary muscle to define a hyperbolic force-velocity curve, with V_{\max} being relatively independent of the initial muscle length but increased by the addition of norepinephrine. Current sophisticated techniques measure contractile activity more accurately.^{65,66}

Isometric Versus Isotonic Contraction

Data for P_0 are obtained under isometric conditions (length unchanged). When muscle is allowed to shorten against a steady load, the conditions are *isotonic* (*iso* = same; *tonic* = contractile force).⁴ Thus the force-velocity curve may be a combination of initial isometric conditions followed by isotonic contraction and then abrupt and total unloading to measure V_{\max} . Although isometric conditions can be found in the whole heart (e.g., during isovolumic contraction), isotonic conditions are rare because afterload is constantly changing during the ejection period and complete unloading is impossible. However, as shortening progresses during ejection, the maximal P_0 declines and velocity is lower for any given nonzero load. Therefore the force-velocity relationship is heuristically useful, but measurements *in vivo* are limited.

Pressure-Volume Loops

Accordingly, measurements of pressure-volume loops are among the best of the current approaches for assessment of the contractile behavior of the intact heart (Fig. 21-22). A crucial measurement is E_s from the pressure-volume relationship.⁴ When the loading conditions are changed, alterations in the slope of this line joining the different E_s points (the end-systolic pressure-volume relationship) are generally a good load-independent index of the contractile performance of the heart. In clinical practice, the need to change the loading conditions and the requirement for invasive monitoring for the full pressure-volume loop lessen the usefulness of this index. Measurement of LV volume adequately and continuously throughout the cardiac cycle is not easy. During a positive inotropic intervention, the pressure-volume loop reflects a smaller end-systolic volume and a

FIGURE 21-22 Pressure-volume loop of the left ventricle. Note the effects of beta-adrenergic catecholamines with both positive inotropic (increased slope of line E_s) and increased lusitropic (relaxant) effects. E_s = slope of the pressure-volume relationship. The total pressure-volume area (for the control area, see *abcd*) is closely related to myocardial oxygen uptake. The area *cde* is the component of work spent in generating potential energy (PE). (Modified from Opie LH: *Heart Physiology, from Cell to Circulation*. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004).

higher end-systolic pressure, so the slope of the pressure-volume relationship (E_s) has moved upward and to the left (Fig. 21-22). When the positive inotropic intervention consist of beta-adrenergic stimulation, the enhanced relaxation (lusitropic effect) results in a lower pressure-volume curve during ventricular filling than in controls.

Power Production and Contractile Function

Power production is another index of contractile function. Power is defined as work per unit time, where F = force and CO = cardiac output:

$$\begin{aligned}\text{Power} &= \text{Work/time} = (F \times \text{cm})/\text{Time} \\ &= \text{Pressure (F/cm}^2) \times \text{CO (cm}^3/\text{Time)}\end{aligned}$$

Power is composed of kinetic and pressure components.¹ The *peak power index* is the maximal power divided by the EDV, which is proposed as a load-independent index of contractile function. Maximum power in turn is approximated by peak aortic flow and systolic pressure, which in practice can be measured invasively as the maximal instantaneous product of pressure and flow.

Limitations of the Concept of Contractility

Despite all the above procedures that can be adopted in an attempt to measure true contractility (or the inotropic state), the concept has at least two serious defects, including (1) the absence of any noninvasive index that can be measured unequivocally and (2) the impossibility of separating the cellular mechanisms of changes in contractile function from those of load or the heart rate.⁴ Thus an increased heart rate, via the changes in Na^+ and Ca^{2+} handling noted earlier, gives rise to increased cytosolic Ca^{2+} transients, and contraction is clearly an inotropic effect, but the simultaneous changes in preload and afterload also involve Frank-Starling effects, which complicates this picture in the clinical setting. Similarly, increased preload involves increased fiber stretch, which in turn causes enhanced myofilament Ca^{2+} sensitivity, a factor that in a sense is built into the Frank-Starling effect, but additional changes in myofilament Ca^{2+} sensitivity (e.g., during acidosis or alpha-adrenergic activation) would be attributed to inotropic changes. *So there is a clear overlap between contractility, which should be independent of load or heart rate, and the effects of load and heart rate on the cellular mechanisms.*^{1,4} Even though this does not undermine the importance of the intrinsic mechanistic distinctions between contractility/inotropy and Frank-Starling mechanisms, the distinction can be blurred by the clinical context and available measurements. For example, in humans with atrial fibrillation and constantly varying ventricular frequency, contractility inferred from pressure-volume loops constantly changes from beat to beat. It is then more difficult to infer a “true” change in LV contractility versus operation of the Frank-Starling mechanism because of varying diastolic filling times.⁴

Left Ventricular Relaxation and Diastolic Dysfunction

Normal diastolic function allows the ventricle to fill adequately during rest and exercise, without an abnormal increase in LA pressure.⁵⁷ As discussed in Chapter 27, the phases of diastole are isovolumic pressure decline and filling. The filling phase is divided into early rapid filling, diastasis, and atrial systole. Early rapid filling contributes 70% to 80% of LV filling in normal individuals. This contribution diminishes with age and various disease states. Early diastolic filling is driven by the LA-to-LV pressure gradient, which is dependent on a complex interplay of factors, including myocardial relaxation, LV elastic recoil, LV diastolic stiffness, LA pressure, ventricular interaction, pericardial constraint, pulmonary vein properties, and mitral orifice area. Diastasis occurs in mid-diastole when LA and LV pressure is usually almost equal. It contributes less than 5% of LV filling, and its duration shortens with tachycardia. In normal subjects, atrial systole contributes 15% to 25% of LV diastolic filling without raising mean LA pressure. This contribution depends on the PR interval, atrial inotropic state, atrial preload, atrial afterload, autonomic tone,

and heart rate. Further details on the basic mechanisms of LV relaxation, as well as measurements of LV relaxation, are covered in Chapter 27.

Right Ventricular Function

Most of the forgoing principles and discussions also apply to the right ventricle, and the differences will not be discussed in any depth here. RV myocytes are fundamentally the same as those in the left ventricle, with some minor, mainly quantitative differences in their ion channel, electrophysiology, Ca^{2+} handling, and myofilament properties. The most important functional differences are in the chamber geometry related to the law of Laplace and the normal levels of pressure developed (lower pressure in the right ventricle and pulmonary circulation).⁶⁸ The right ventricle has a larger radius of curvature, which would tend to increase wall tension, but it normally develops much lower pressure, which greatly reduces wall tension (wall tension = $[\text{radius} \times \text{pressure}]/[2 \times \text{thickness}]$). RV wall thickness is also lower such that the normal characteristics of RV shape and size are functionally matched to the different prevailing conditions on the right ventricle. However, just as systemic hypertension increases LV wall stress, pulmonary hypertension (independent of but also secondary to LV overload) can cause increased wall stress and all of the same functional sequelae.⁶⁷

Atrial Function

The left atrium has five main functions.^{4,67} First and best known, the left atrium functions as a blood-receiving reservoir chamber. Second, it also is a contractile chamber that by presystolic contraction helps complete LV filling with an atrial kick. Third, it functions as a conduit that empties its contents into the left ventricle down a pressure gradient after the mitral valve opens. Fourth, it is a *blood volume sensor* in the heart and releases atrial natriuretic peptide (ANP) in response to stretch so that ANP-induced diuresis can help restore blood volume to normal. Notably, in congestive heart failure when the renin-angiotensin system causes fluid retention and exacerbates the elevation in LA pressure and volume, ANP secretion is elevated. Fifth and finally, the atrium contains receptors for the afferent arms of various reflexes, including mechanoreceptors that increase the sinus discharge rate, thereby contributing to the tachycardia of exercise as venous return increases (Bainbridge reflex).^{1,4}

The atrial pressure-volume loop is very different in shape from that of the ventricles in that it resembles a figure of eight. During atrial pacing, preload is increased and the atria are distended, so the volume part of the loop is small and the pressure part of the loop is much enlarged.⁶⁸ The atria have a number of differences in structure and function from the ventricles, including smaller myocytes with fewer T tubules, a shorter action potential duration, and more fetal myosin isoforms (both heavy and light chains).⁶⁹ The more rapid atrial repolarization is due to increased outward potassium currents, such as I_{to} , and also has faster Ca^{2+} transient kinetics. In general, these histologic and physiologic changes might be related to the decreased need for the atria to generate high intrachamber pressures rather being sensitive to changes in volume while retaining enough contractile action to help with LV filling and to respond to inotropic stimuli. *Atrial remodeling* refers to a variety of ionic, structural, contractile, and metabolic changes that are induced by insults such as chronic atrial tachyarrhythmias, including atrial fibrillation,⁶⁹ or by left atrial stretch and enlargement. Cellular mechanisms include decreased L-type Ca^{2+} channel activity,⁶⁹ increased abnormal collagen,⁷⁰ and probably adverse stretch-induced signaling. The results include poor contractile performance and increased initiation and perpetuation of atrial fibrillation.

FUTURE PERSPECTIVES

During the last 20 years we have gained tremendous molecular and cellular insight into a much richer, quantitatively detailed understanding of the individual steps in the overall excitation-contraction-relaxation coupling process. In addition, there is a greatly enhanced

understanding about how all these processes interact at the cellular and tissue level, how they are regulated by numerous interacting signaling pathways, and what goes wrong during certain cardiac pathologies. This is a very complex system, and diseases such as heart failure are also extremely complex. In the coming 5 years we can expect further clarification of all these systems, and one area will probably be better understanding of signaling in local microdomains and protein complexes. However, we must also in the meantime use the rich mechanistic knowledge that we now have to test novel therapeutic strategies for heart failure (e.g., SERCA2 overexpression, RyR inhibitors, β ARK inhibitors, myofilament enhancers). This work may provide novel effective therapies but will also help us better understand how the fundamental systems that we are perturbing with these approaches really integrate into behavior of the whole system. This emphasizes how critical it is to integrate our knowledge of these many systems that dynamically regulate contraction and relaxation over multiple physical scales (molecules to cell to heart to animal) and time scales (milliseconds to seconds, minutes, hours, days, and years), as well as multiple disciplinary and methodologic perspectives to help bring the entire system to a higher level of integrated understanding. In this way the therapeutic strategies that we must also continue to test along the way are likely to improve.

OVERVIEW

Despite repeated attempts to discover a unique pathophysiologic mechanism that precisely explains the clinical syndrome of heart failure, no single conceptual paradigm has withstood the test of time. Although clinicians initially viewed heart failure as a problem of excessive salt and water retention that was caused by abnormalities of renal blood flow (the so-called cardiorenal model) and/or abnormal pumping capacity of the heart (the cardiocirculatory or hemodynamic model),¹ these models do not adequately explain the relentless disease progression that occurs in this syndrome.

This chapter focuses on the molecular and cellular changes that underlie heart failure with depressed systolic function, with an emphasis on the role of neurohormonal activation and left ventricular (LV) remodeling as the primary determinants for disease progression in heart failure. The hemodynamic, contractile, and wall motion disorders in heart failure are discussed in the chapters on echocardiography (see Chapter 14), cardiac catheterization (see Chapter 19), radionuclide imaging (see Chapter 16), and clinical assessment of the patient with heart failure (see Chapter 23). The pathogenesis of heart failure with a normal ejection fraction is discussed elsewhere in this book (see Chapter 27).

PATHOGENESIS

As shown in Figure 22-1A, heart failure may be viewed as a progressive disorder that is initiated after an *index event* either damages the heart muscle, with a resultant loss of functioning cardiac myocytes or, alternatively, disrupts the ability of the myocardium to generate force, thereby preventing the heart from contracting normally. This index event may have an abrupt onset, as in the case of a myocardial infarction; it may have a gradual or insidious onset, as in the case of hemodynamic pressure or volume overloading, or it may be hereditary, as in the case of many of the genetic cardiomyopathies. Regardless of the nature of the inciting event, the feature that is common to each of these index events is that they all, in some manner, produce a decline in pumping capacity of the heart. In most instances, patients will remain asymptomatic or minimally symptomatic after the initial decline in pumping capacity of the heart, or symptoms develop only after the dysfunction has been present for some time. Although the precise reasons why patients with LV dysfunction remain asymptomatic have not been established with certainty, one potential explanation is that a number of compensatory mechanisms that become activated in the setting of cardiac injury or depressed cardiac output appear to modulate LV function within a physiologic/homeostatic range, such that the patient's functional capacity is preserved or is depressed only minimally. With progression to symptomatic heart failure, however, the sustained activation of neurohormonal and cytokine systems leads to a series of end-organ changes within the myocardium referred to collectively as *LV remodeling*. As discussed further on, LV remodeling is sufficient to lead to disease progression in heart failure independent of the neurohormonal status of the patient.

HEART FAILURE AS A PROGRESSIVE MODEL

Neurohormonal Mechanisms

A growing body of experimental and clinical evidence suggests that heart failure progresses as a result of the overexpression of biologically active molecules that are capable of exerting deleterious effects on the heart and circulation (Fig. 22-1B).¹ The portfolio of compensatory mechanisms that have been described thus far includes activation of the adrenergic nervous system and the renin-angiotensin system (RAS), which are responsible for maintaining cardiac output through increased retention of salt and water; peripheral arterial vasoconstriction and increased contractility; and inflammatory mediators that are responsible for cardiac repair and remodeling. It bears emphasis that *neurohormone* is largely a historical term, reflecting the original observation that many of the molecules that were elaborated in heart failure were produced by the neuroendocrine system and thus acted on the heart in an endocrine manner. It has since become apparent, however, that a great many of the so-called classical neurohormones such as norepinephrine (NE) and angiotensin II are synthesized directly within the myocardium by myocytes and thus act in an autocrine and paracrine manner. Nonetheless, the important unifying concept that arises from the neurohormonal model is that the overexpression of portfolios of biologically active molecules contributes to disease progression by virtue of the deleterious effects these molecules exert on the heart and circulation.

Activation of the Sympathetic Nervous System

The decrease in cardiac output in heart failure activates a series of compensatory adaptations that are intended to maintain cardiovascular homeostasis. One of the most important adaptations is activation of the sympathetic (adrenergic) nervous system, which occurs early in the course of heart failure. Activation of the sympathetic nervous system in heart failure is accompanied by a concomitant withdrawal of parasympathetic tone (Fig. e22-1). Although these disturbances in autonomic control initially were attributed to loss of the inhibitory input from arterial or cardiopulmonary baroreceptor reflexes, increasing evidence indicates that excitatory reflexes also may participate in the autonomic imbalance that occurs in heart failure.² Under normal conditions, inhibitory inputs from “high-pressure” carotid sinus and aortic arch baroreceptors and the “low-pressure” cardiopulmonary mechanoreceptors are the principal inhibitors of sympathetic outflow, whereas discharge from the non-baroreflex peripheral chemoreceptors and that from muscle *metaboreceptors* are the major excitatory inputs to sympathetic outflow. The vagal limb of the baroreceptor heart rate reflex also is responsive to arterial baroreceptor afferent inhibitory input. Healthy persons display low sympathetic discharge at rest and have a high heart rate variability. In patients with heart failure, however, inhibitory input from baroreceptors and mechanoreceptors decreases and excitatory input increases, with the net result of a generalized increase in sympathetic nerve traffic and blunted parasympathetic nerve traffic, leading to loss of heart rate variability and increased peripheral vascular resistance.²

FIGURE e22-1 Compensated and decompensated heart failure, as indicated by the presence or absence of urinary sodium retention, together with symptoms and signs of expanded intravascular and extravascular volume. **A**, In compensated heart failure with mild to moderate reductions in renal perfusion, natriuretic peptides, such as atrial natriuretic peptide (ANP) released by distended atria, stimulate sodium excretion (decreasing reabsorption, *minus sign*) so that the urinary sodium-potassium ratio is greater than 1.0. **B**, In decompensated heart failure, moderate to severe reductions in renal perfusion activate the renin-angiotensin-aldosterone system (RAAS), overriding the action of natriuretic peptides to stimulate nearly complete urinary sodium reabsorption (*plus sign*), resulting in a urinary sodium-potassium ratio less than 1.0. ACh = acetylcholine; CNS = central nervous system; E = epinephrine. (From Weber KT: Aldosterone in congestive heart failure. *N Engl J Med* 345:1689, 2001; and Weber KT, Villareal D: Aldosterone and antialdosterone therapy in congestive heart failure. *Am J Cardiol* 71[suppl 3A]:11A, 1993.)

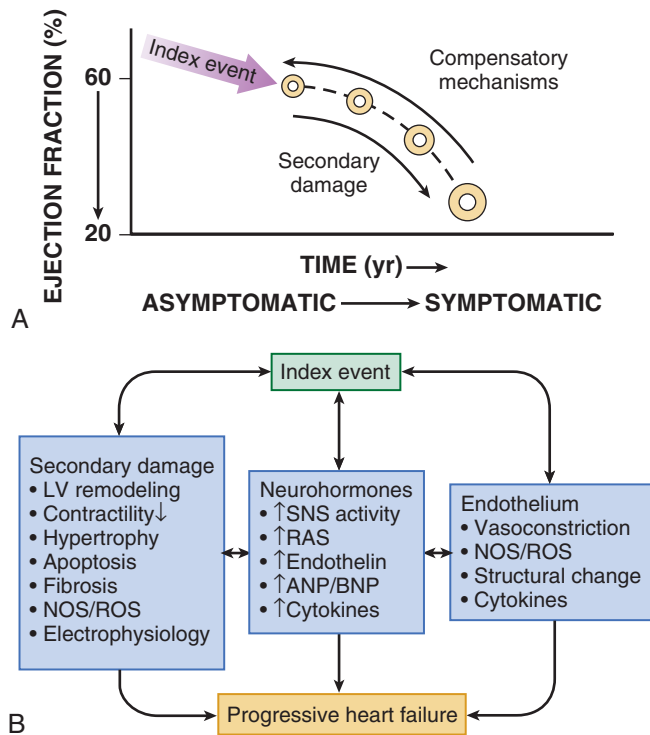

FIGURE 22-1 Pathogenesis of heart failure. **A**, Heart failure begins after a so-called index event produces an initial decline in pumping capacity of the heart. **B**, After this initial decline in pumping capacity of the heart, a variety of compensatory mechanisms are activated, including the adrenergic nervous system, the RAS, and the cytokine systems. In the short term, these systems are able to restore cardiovascular function to a normal homeostatic range, with the result that the patient remains asymptomatic. With time, however, the sustained activation of these systems can lead to secondary end-organ damage within the ventricle, with worsening LV remodeling and subsequent cardiac decompensation. As a result of these changes, patients undergo the transition from asymptomatic to symptomatic heart failure. ANP/BNP = atrial natriuretic peptide/brain type natriuretic peptide; NOS/ROS = nitric oxide synthase/reactive oxygen species; SNS = sympathetic nervous system. (From Mann DL: *Mechanisms and models in HF: a combinatorial approach*. *Circulation* 100:99, 1999; and Kaye DM, Krum H: *Drug discovery for heart failure: A new era or the end of the pipeline?* *Nat Rev Drug Discov* 6:127, 2007.)

As a result of the increase in sympathetic tone, there is an increase in circulating levels of NE, a potent adrenergic neurotransmitter. The elevated levels of circulating NE result from a combination of increased release of NE from adrenergic nerve endings and its consequent “spillover” into the plasma, as well as reduced uptake of NE by adrenergic nerve endings. In patients with advanced heart failure, the circulating levels of NE in resting patients are two to three times those found in normal subjects. Indeed, plasma levels of NE predict mortality in patients with heart failure. Whereas the normal heart usually extracts NE from the arterial blood, in patients with moderate heart failure the coronary sinus NE concentration exceeds the arterial concentration, indicating increased adrenergic stimulation of the heart. However, as heart failure progresses there is a significant decrease in the myocardial concentration of NE. The mechanism responsible for cardiac NE depletion in severe heart failure is not clear and may relate to an “exhaustion” phenomenon resulting from the prolonged adrenergic activation of the cardiac adrenergic nerves in heart failure. In addition, there is decreased activity of myocardial tyrosine hydroxylase, which is the rate-limiting enzyme in the synthesis of NE. In patients with cardiomyopathy, iodine-131-labeled metaiodobenzylguanidine (MIBG), a radiopharmaceutical that is taken up by adrenergic nerve endings, is not taken up normally, suggesting that NE reuptake also is impaired in heart failure.

Increased sympathetic activation of the β_1 -adrenergic receptor results in increased heart rate and force of myocardial contraction, with a resultant increase in cardiac output (see Chapter 21). In addition, the heightened activity of the adrenergic nervous system leads to stimulation of myocardial α_1 -adrenergic receptors, which

elicits a modest positive inotropic effect, as well as peripheral arterial vasoconstriction (Fig. 22-2). Although NE enhances both contraction and relaxation and maintains blood pressure, myocardial energy requirements are augmented, which can intensify ischemia when myocardial O_2 delivery is restricted. The augmented adrenergic outflow from the central nervous system also may trigger ventricular tachycardia or even sudden cardiac death, particularly in the presence of myocardial ischemia. Thus activation of the sympathetic nervous system provides short-term support that has the potential to become maladaptive over the long term (see Fig. 22-2). Moreover, increasing evidence suggests that apart from the deleterious effects of sympathetic activation, parasympathetic withdrawal also may contribute to the pathogenesis of heart failure. Withdrawal of parasympathetic nerve stimulation has been associated with decreased nitric oxide (NO) levels, increased inflammation, increased sympathetic activity and worsening LV remodeling. Two ongoing clinical trials, INOVATE-HF (Increase of Vagal Tone in CHF) (NCT01303718) and NECTAR-HF (Neural Cardiac Therapy for Heart Failure Study) (NCT01385176), are examining the effects of vagal nerve stimulation on LV structure and clinical outcomes in patients with New York Heart Association (NYHA) class III heart failure.

Activation of the Renin-Angiotensin System

In contrast with the sympathetic nervous system, the components of the RAS are activated comparatively later in heart failure. The presumptive mechanisms for RAS activation in heart failure include renal hypoperfusion, decreased filtered sodium reaching the macula densa in the distal tubule, and increased sympathetic stimulation of the kidney, leading to increased renin release from juxtaglomerular apparatus (Fig. 22-3). As shown in Figure 22-4, renin cleaves four amino acids from circulating angiotensinogen, which is synthesized in the liver, to form the biologically inactive decapeptide angiotensin I. Angiotensin-converting enzyme (ACE) cleaves two amino acids from angiotensin I to form the biologically active octapeptide(1-8) angiotensin II. Most ACE activity (approaching 90%) in the body is found in tissues; the remaining 10% is found in a soluble (non-membrane-bound) form in the interstitium of the heart and vessel wall. The importance of tissue ACE activity in heart failure is suggested by the observation that ACE messenger RNA (mRNA) and ACE-binding sites and ACE activity are increased in explanted human hearts.³ Angiotensin II also can be synthesized using renin-independent pathways through the enzymatic conversion of angiotensinogen to angiotensin I by kallikrein and cathepsin G (see Fig. 22-4). The tissue production of angiotensin II also may occur along ACE-independent pathways, through the activation of chymase. This latter pathway may be of major importance in the myocardium, particularly when the levels of renin and angiotensin I are increased by the use of ACE inhibitors. Angiotensin II itself can undergo further proteolysis to generate three biologically active fragments: angiotensin III²⁻⁸ and angiotensin IV,³⁻⁸ which promote vasoconstriction,⁴ and angiotensin¹⁻⁷ which may act to counteract the deleterious effects of angiotensin II on endothelial function.

Angiotensin II exerts its effects by binding to two G protein-coupled receptors, the angiotensin type 1 (AT_1) and angiotensin type 2 (AT_2) receptors. The predominant angiotensin receptor in the vasculature is the AT_1 receptor. Although both the AT_1 and AT_2 receptor subtypes are present in human myocardium, the AT_2 receptor predominates in a 2:1 molar ratio. Cellular localization of the AT_1 receptor in the heart is most abundant in nerves distributed in the myocardium, whereas the AT_2 receptor is localized more specifically in fibroblasts and the interstitium. Activation of the AT_1 receptor leads to vasoconstriction, cell growth, aldosterone secretion, and catecholamine release, whereas activation of the AT_2 receptor leads to vasodilation, inhibition of cell growth, natriuresis, and bradykinin release. Studies have shown that the AT_1 receptor and mRNA levels are downregulated in failing human hearts, whereas AT_2 receptor density is increased or unchanged, so that the ratio of AT_1 to AT_2 receptors decreases.⁴

Angiotensin II has several important actions that are critical to maintaining short-term circulatory homeostasis (see further on). The sustained expression of angiotensin II is maladaptive, however,

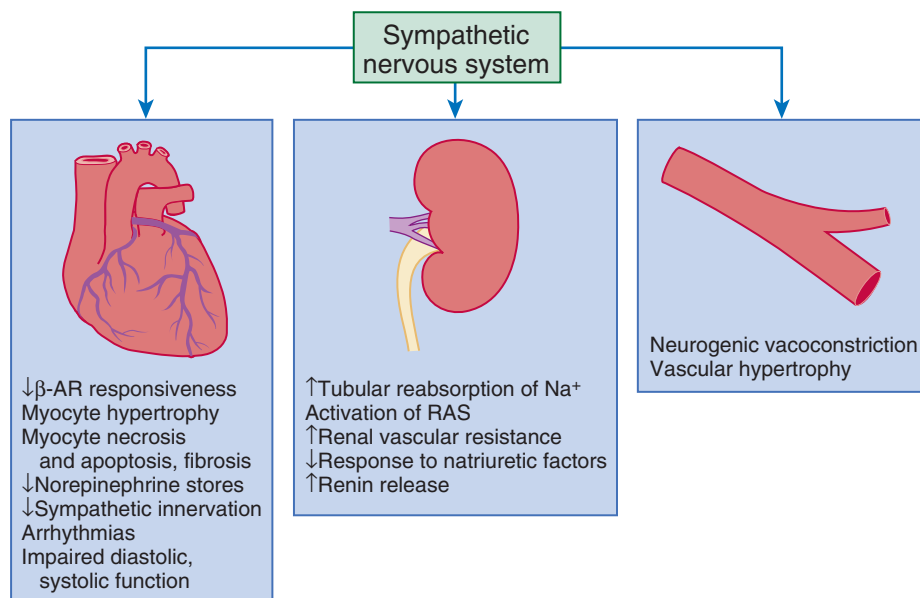

FIGURE 22-2 Activation of the sympathetic nervous system. Increased sympathetic nervous system activity may contribute to the pathophysiology of congestive heart failure by multiple mechanisms involving cardiac, renal, and vascular function. In the heart, increased sympathetic nervous system outflow may lead to desensitization β-adrenergic receptors (β-ARs), myocyte hypertrophy, necrosis, apoptosis, and fibrosis. In the kidneys, increased sympathetic activation induces arterial and venous vasoconstriction, activation of the renin-angiotensin system (RAS), increase in salt and water retention, and an attenuated response to natriuretic factors. In the peripheral vessels, neurogenic vasoconstriction and vascular hypertrophy are induced by increased sympathetic nervous activity. (From Nohria A, Cusco JA, Creager MA: *Neurohormonal, renal and vascular adjustments in heart failure*. In Colucci WS [ed]: *Atlas of Heart Failure*. 4th ed. Philadelphia, Current Medicine LLC, 2008, p 106.)

FIGURE 22-3 Activation of the RAS. The RAS is activated in patients with heart failure. The major site of release of circulating renin is the juxtaglomerular apparatus of the kidney, where multiple stimuli may contribute to renal release of renin into the systemic circulation, including renal sympathetic efferent activity, decreased distal sodium delivery, reduced renal perfusion pressure, and diuretic therapy. Natriuretic peptides (ANP, BNP) and vasopressin (dashed arrows) may inhibit the release of renin. Renin enzymatically cleaves angiotensinogen to form angiotensin II from angiotensin I. Angiotensin II is a potent vasoconstrictor and promotes sodium resorption by increasing aldosterone secretion and through a direct effect on the tubules. Angiotensin II also stimulates water intake by directly acting on the thirst center. (From Nohria A, Cusco JA, Creager MA: *Neurohormonal, renal and vascular adjustments in heart failure*. In Colucci WS [ed]: *Atlas of Heart Failure*. 4th ed. Philadelphia, Current Medicine LLC, 2008, p 107.)

leading to fibrosis of the heart, kidneys, and other organs. Angiotensin II can also lead to worsening neurohormonal activation by enhancing the release of NE from sympathetic nerve endings, as well as stimulating the zona glomerulosa of the adrenal cortex to produce aldosterone. Analogous to angiotensin II, aldosterone provides short-term support to the circulation by promoting the reabsorption of sodium in exchange for potassium, in the distal segments of the nephron. However, the sustained expression of aldosterone may exert harmful effects by provoking hypertrophy and fibrosis within the vasculature and the myocardium, contributing to reduced vascular compliance and increased ventricular stiffness. In addition, aldosterone provokes endothelial cell dysfunction, baroreceptor dysfunction, and inhibition of NE uptake, any or all of which may lead to worsening of heart failure. The mechanism of action of aldosterone in the cardiovascular system appears to involve oxidative stress, with resultant inflammation in target tissue.

Oxidative Stress. Reactive oxygen species (ROS) are a normal byproduct of aerobic metabolism. In the heart, the potential sources for ROS include the mitochondria, xanthine oxidase, and nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase (Fig. 22-5). ROS can modulate the activity of a variety of intracellular proteins and signaling pathways, including essential proteins involved in myocardial excitation-contraction coupling, such as ion channels, sarcoplasmic reticulum (SR) calcium release channels, and myofilament proteins, as well as signaling pathways that are coupled to myocyte growth.⁵ "Oxidative stress" occurs when the production of ROS exceeds the buffering capacity of antioxidant defense systems, leading to an excess of ROS within the cell. Substantial evidence indicates that the level of oxidative stress is increased both systemically and in the myocardium of patients with heart failure. Oxidative stress in the heart may be due to reduced antioxidant capacity and/or the increased production of ROS, which may arise secondary to mechanical strain of the myocardium, neurohormonal stimulation (angiotensin II, α-adrenergic agonists, endothelin-1 [ET-1]) and/or inflammatory

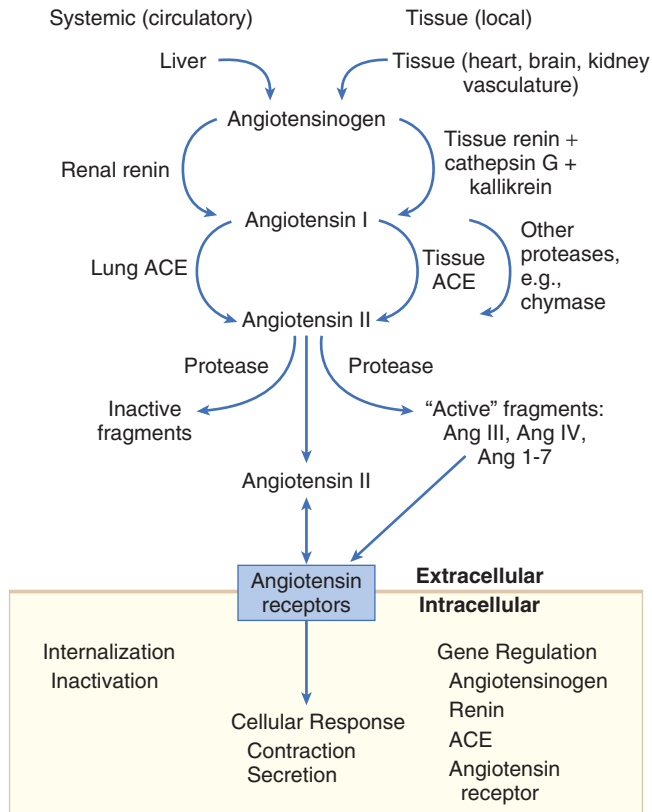

FIGURE 22-4 The systemic and tissue components of the RAS. Several tissues, including myocardium, vasculature, kidney, and brain, have the capacity to generate angiotensin II independent of the circulating RAS. Angiotensin II produced at the tissue level may play an important role in the pathophysiology of heart failure. ANG = angiotensin. (Modified from Timmermans PB, Wong PC, Chiu AT, et al: Angiotensin II receptors and angiotensin II receptor antagonists. *Pharmacol Rev* 45:205, 1993.)

FIGURE 22-5 Cellular sources of ROS and ROS signaling in cardiac hypertrophy. ROS-generating systems are shown on the left and include xanthine oxidase, NADPH oxidases (NOX2, NOX4), NOS, and mitochondrial complexes. ROS activation has protean effects on calcium handling, myofilament function, matrix activation, kinase and phosphatase stimulation, and transcriptional regulation of matrix metalloproteinases (MMPs). Akt = protein kinase B; ASK-1 = apoptosis signal-regulating kinase 1; ETR = endothelin receptor; 5HTMF = 5 hydrotetramethylpholate; LTCC = L-type calcium channel; MAPK = mitogen-activated protein kinase; NF-κB = nuclear factor-kappaB; PKC = protein kinase C; PI3K = phosphatidylinositol 3 kinase; PLB = phospholamban; RyR = ryanodine receptor; SERCA2 = sarcoplasmic reticulum Ca²⁺ ATPase. cytokines (tumor necrosis factor [TNF], interleukin [IL]-1. Excessive mitochondria-derived ROS in cardiac myocytes have been demonstrated in experimental models of heart failure and may contribute to contractile dysfunction in advanced heart failure. Increased xanthine oxidase expression and activity have been reported in canine rapid pacing-induced heart failure and patients with end-stage heart failure. Moreover, increased expression and activity of myocardial NADPH oxidases have recently been demonstrated in both experimental and human heart failure.⁵ In cultured cardiac myocytes ROS stimulate myocyte hypertrophy, reexpression of fetal gene programs, and apoptosis. ROS also can modulate fibroblast proliferation and collagen synthesis, and can trigger increased matrix metalloproteinase (MMP) abundance and activation. ROS also can affect the peripheral vasculature in heart failure by decreasing the bioavailability of NO. These and other observations have led to the suggestion that strategies to reduce ROS may be of therapeutic value in patients with heart failure. The NIH-sponsored EXACT-HF (NCT00987415) trial is examining the role of allopurinol in NYHA class II to IV heart failure patients with serum uric acid levels of 9.5 mg/dL or greater (a marker of oxidative stress).

The importance of aldosterone, independent of angiotensin II, has been demonstrated by clinical trials (see Chapter 25) showing that low-dose spironolactone increased the survival of patients with NYHA class II to IV systolic heart failure, as well as improved survival after myocardial infarction, independent of changes in volume or electrolyte status.⁶

Neurohormonal Alterations of Renal Function

One of the signatures of advancing heart failure is increased salt and water retention by the kidneys. Traditional theories have ascribed this increase to either "forward" failure, which attributes sodium retention to inadequate renal perfusion as a consequence of impaired cardiac output, or "backward" failure, which emphasizes the importance of increased venous pressure in favoring transudation of salt and water from the intravascular to the extracellular compartment. These mechanisms have largely been supplanted by the concept of decreased effective arterial blood volume, which postulates that

despite blood volume expansion in heart failure, inadequate cardiac output sensed by baroreceptors in the vascular tree leads to a series of compensatory neurohormonal adaptations that resemble the homeostatic response to acute blood loss.⁷ As illustrated in Figure 22-6, a falling cardiac output and/or redistribution of the circulating blood volume is sensed by baroreceptors in the left ventricle, the aortic arch, the carotid sinus and the renal afferent arterioles. The loss of inhibitory input from arterial or cardiopulmonary baroreceptor reflexes leads to sustained activation of the sympathetic nervous and the renin-angiotensin systems. The ongoing XR-1 trial (NCT01484288) is using an implantable barostimulation device that activates the carotid baroreceptors to decrease sympathetic activation in patients with symptomatic heart failure, to determine whether this will restore the sympathovagal imbalance.

There is little evidence to suggest that a primary renal abnormality is responsible for excessive sodium retention in heart failure. Rather, volume overload in heart failure probably is secondary to a functional derangement of renal physiology in response to several factors that have the potential to cause increased sodium reabsorption, including activation of the sympathetic

FIGURE 22-6 Unloading of high-pressure baroreceptors (circles) in the left ventricle, carotid sinus, and aortic arch generates afferent signals that stimulate cardioregulatory centers in the brain, resulting in the activation of efferent pathways in the sympathetic nervous system. The sympathetic nervous system appears to be the primary integrator of the neurohumoral vasoconstrictor response to arterial underfilling. Activation of renal sympathetic nerves stimulates the release of AVP. Sympathetic activation also causes peripheral and renal vasoconstriction, as does angiotensin II. Angiotensin II constricts blood vessels and stimulates the release of aldosterone from the adrenal gland, and it also increases tubular sodium reabsorption and causes remodeling of cardiac myocytes. Aldosterone also may have direct cardiac effects, in addition to increasing the reabsorption of sodium and the secretion of potassium and hydrogen ions in the collecting duct. The black arrows designate circulating hormones. (Modified from Schrier RW, Abraham WT: *Hormones and hemodynamics in heart failure*. *N Engl J Med* 341:577, 1999.)

nervous system, activation of RAS, reduced renal perfusion pressures, and blunting of renal responsiveness to natriuretic peptides. Increased renal sympathetic nerve-mediated vasoconstriction leads to decreased renal blood flow, as well as increased renal tubular sodium and water reabsorption throughout the nephron. Renal sympathetic stimulation also can lead to the nonosmotic release of arginine vasopressin (AVP) from the posterior pituitary, which reduces the excretion of free water and contributes to worsening peripheral vasoconstriction, as well as increased ET production.⁷

Arginine Vasopressin. AVP is a pituitary hormone that plays a central role in the regulation of free water clearance and plasma osmolality (see Fig. 22-6). Under normal circumstances, AVP is released in response to an increase in plasma osmolality, leading to increased retention of water from the collecting duct. Of note, circulating AVP is elevated in many patients with heart failure, even after correction for plasma osmolality (i.e., nonosmotic release),⁷ and may contribute to the hyponatremia that occurs in heart failure. The cellular effects of AVP are mediated mainly by interactions with three types of receptors, termed V_{1a} , V_{2a} , and V_2 . The V_{1a} receptor is the most widespread subtype, and is found in primarily in vascular smooth muscle cells. The V_{1b} receptor has a more limited distribution and is located mainly in the central nervous system. The V_2 receptors are found primarily in the epithelial cells in the renal collecting duct and the thick ascending limb. AVP receptors are members of the G protein-coupled receptors. The V_{1a} receptors mediate

vasoconstriction, platelet aggregation, and stimulation of myocardial growth factors, whereas V_{1b} modulates adrenocorticotrophic hormone (ACTH) secretion from the anterior pituitary and the V_2 receptor mediates antidiuretic effects by stimulating adenylyl cyclase to increase the rate of insertion of water channel-containing vesicles into the apical membrane. Because the vesicles contain pre-formed functional water channels, termed aquaporins, their localization in the apical membranes in response to V_2 stimulation increases the water permeability of the apical membrane, leading to water retention. The “vaptans,” vasopressin receptor antagonists with V_{1a} (relcovaptan) or V_2 (tolvaptan, lixivaptan) selectivity or non-selective V_{1a}/V_2 activity (conivaptan), have been shown to reduce body weight and reduce hyponatremia in clinical trials (see also Chapters 24 and 25).

Increased renal sympathetic activity leads to increased renin production by the kidneys, with a resultant sustained activation of RAS, despite an expanded extracellular volume (see Fig. 22-3). Angiotensin II facilitates retention of sodium and water by multiple renal mechanisms, including a direct proximal tubular effect, as well as through activation of aldosterone, which leads to increased sodium resorption in the distal tubule. Angiotensin II also stimulates the thirst center of the brain and provokes the release of AVP and aldosterone, which both can lead to further dysregulation of salt and water homeostasis.

A number of counterregulatory neurohormonal systems become activated in heart failure in order to offset the deleterious effects of the vasoconstricting neurohormones (Table e22-1). Metabolites of vasodilatory prostaglandins, including prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2), are elevated in patients with heart failure. In addition to being a vasodilator, PGE_2 enhances renal sodium excretion and modulates the antidiuretic action of AVP. One class of the most important counterregulatory neurohormonal systems that become activated in heart failure are the natriuretic peptides, including atrial natriuretic peptide (ANP) and brain type natriuretic peptide (BNP). Under physiologic conditions, ANP and BNP function as natriuretic hormones that are released in response to increases in atrial and/or myocardial stretch, often secondary to excessive sodium intake. Once released, these cardiac peptides act on the kidney and peripheral circulation to unload the heart, through increased excretion of sodium and water, while inhibiting the release of renin and aldosterone. In the setting of RAS activation, the release of ANP and BNP may serve as an important counterregulatory mechanism that maintains sodium and water homeostasis. However, for reasons that are not entirely clear, the renal effects of the natriuretic peptides appear to become blunted with advancing heart failure, leaving the effects of RAS unopposed.⁸ Potential reasons for this blunting include low renal perfusion pressure, relative deficiency or altered molecular forms of the natriuretic peptides, and decreased levels of natriuretic peptide receptors.

Natriuretic Peptides. The natriuretic peptide system consists of five structurally similar peptides collectively termed ANP, urodilantin (an isoform of ANP), BNP, C-type natriuretic peptide (CNP), and dendroaspis natriuretic peptide (DNP)⁹ (Fig. 22-7A). ANP, a 28-amino-acid peptide hormone, is produced principally in the cardiac atria, whereas

BNP, a 32-amino-acid peptide originally isolated from porcine brain, was later identified as a hormone that was primarily produced in the cardiac ventricles.⁹ Both ANP and BNP are secreted in response to increasing cardiac wall tension; however, other factors such as neurohormones (e.g., angiotensin II, ET-1) or physiologic factors (e.g., age, sex, renal function) may also play a role in their regulation. The biosynthesis, secretion and clearance of BNP differs from ANP, suggesting that these two natriuretic peptides have discrete physiologic and pathophysiologic roles. Whereas ANP is secreted in short bursts in response to acute changes in atrial pressure, the activation of BNP is regulated transcriptionally in response to chronic increases in atrial/ventricular pressure. ANP and BNP initially are synthesized as prohormones that are subsequently proteolytically cleaved, respectively, by corin and furin, to yield large, biologically inactive N-terminal fragments (NT-ANP and NT-BNP) and smaller, biologically active peptides (ANP and BNP). ANP has a relatively short half-life of approximately 3 minutes, whereas BNP has a plasma half-life of approximately 20 minutes. C-type natriuretic peptide (CNP), which is located primarily in the vasculature, also is released as a prohormone that is cleaved into biologically inactive form (NT-CNP) and a 22-amino-acid biologically active form (i.e., CNP).

Figure 22-7B illustrates the signaling pathway of the natriuretic peptide system. The natriuretic peptides stimulate the production of the intracellular second messenger cyclic guanosine monophosphate (cGMP), via binding to the natriuretic peptide A receptor (NPR-A), which preferentially binds ANP and BNP, and the natriuretic peptide B receptor (NPR-B), which preferentially binds CNP. Both NPR-A and NPR-B receptor are coupled to particulate guanylate cyclase. Activation of NPR-A and NPR-B results in natriuresis, vasorelaxation, inhibition of renin and aldosterone, inhibition of fibrosis, and increased lusitropy. The natriuretic peptide C receptor (NPR-C) is not linked to cGMP and serves as a clearance receptor for the natriuretic peptides. Natriuretic peptides are degraded by neutral endopeptidase (NEP) 24.11 (nephilysin), which is widely expressed in multiple tissues, where it often is colocalized with ACE. Inhibition of NEP may further potentiate the renal actions of ANP and BNP. The experience with omapatrilat, which inhibited both neutral endopeptidase and ACE, showed that omapatrilat was no more effective than ACE inhibitor alone in patients with heart failure.¹⁰ However, the use of a combined AT₁ receptor antagonist and a nephilysin inhibitor (LCZ696) was shown to have a favorable impact on LV structure in patients with heart failure and a preserved ejection fraction (see Chapter 27).

The biologic importance of the natriuretic peptides in renal sodium handling has been demonstrated in multiple studies using natriuretic peptide receptor antagonists, as well as overexpression of ANP or BNP. In experimental heart failure models, either acute blockade of the

natriuretic A and B receptors or chronic genetic disruption of the natriuretic peptide A receptor blunts the renal natriuretic response to acute volume expansion, demonstrating the renal protective action of natriuretic peptide activation. The infusion of a recombinant human ANP and BNP exerts beneficial hemodynamic effects that are characterized by decreases in arterial and venous pressures, an increase in cardiac output, and suppression of neurohormonal activation in humans, resulting in their clinical development as therapeutic agents for human heart failure (see Chapter 24). In addition to their important biologic role, the natriuretic peptides have provided important diagnostic and prognostic information in heart failure (see Chapter 23).

Neurohormonal Alterations in the Peripheral Vasculature

In patients with heart failure, the complex interactions between the autonomic nervous system and local autoregulatory mechanisms tend to preserve circulation to the brain and heart while decreasing blood flow to the skin, skeletal muscles, splanchnic organs, and kidneys. This intense visceral vasoconstriction during exercise helps to divert the limited cardiac output to exercising muscle but contributes to hypoperfusion of the gut and kidneys. The most powerful stimulus for peripheral vasoconstriction is sympathetic activation, which releases the potent vasoconstrictor NE. Other vasoconstrictors that contribute to maintaining circulatory homeostasis include angiotensin II, ET, neuropeptide Y, urotensin II, thromboxane A₂, and AVP (see Table e22-1). The increased sympathetic adrenergic stimulation of the peripheral arteries and the increased concentrations of circulating vasoconstrictors contribute to the arteriolar vasoconstriction and to the maintenance of arterial pressure, while the sympathetic stimulation of the veins contributes to an increase in venous tone, which helps to maintain venous return and ventricular filling and to support cardiac performance by Starling's law of the heart (Chapter 21).

Endothelin. The three ET peptides—ET-1, ET-2, and ET-3—all are potent vasoconstrictors. Although released primarily by endothelial cells, ET also can be synthesized and released by a variety of other cell types such as cardiac myocytes. ET-1 is the predominant isoform of the ET peptide family and is ubiquitously expressed. ET-1 is synthesized as a protein precursor termed preproET-1. Preproendothelin-1 is processed by multiple proteases in a process that involves the proteolytic

release of proendothelin-1 ("big endothelin"), followed by C-terminal trimming by a carboxypeptidase and further processing by endothelin-converting enzyme (ECE) to generate the biologically active 21-amino-acid ET-1 peptide. However, studies in ECE-knockout mice have confirmed the presence of significant levels of mature ET-1, suggesting that there may be alternative ECE-independent (e.g., chymase, non-ECE metalloproteinases) pathways for generation of ET-1. At least two subtypes of ET receptors, designated A and B, have been identified in human myocardium. Endothelin ET(A) receptors mediate vasoconstriction, cell proliferation, pathologic hypertrophy, fibrosis, and increased contractility, whereas ET(B) receptors are involved in the clearance of ET-1 and the release of NO and prostacyclin. The release of ET from endothelial cells *in vitro* can be enhanced by several vasoactive agents (e.g., NE, angiotensin II, thrombin) and cytokines (e.g., TGF- β , TNF, and IL-1). Several reports have documented an increase in circulating levels of ET-1 in patients with heart failure and have shown that ET levels correlate with patient outcomes. Furthermore, plasma ET concentrations correlate directly with pulmonary artery pressure and pulmonary vascular resistance. Based on the biologic properties of ET, ET receptor antagonists were developed for the treatment of patients with heart failure. Although early experimental studies showed that ET(A) receptor antagonists inhibited myocardial hypertrophy in rats with pressure overload-induced hypertrophy caused by aortic banding and prevented cardiac remodeling in rats with myocardial infarction, and although early clinical studies confirmed the ability of these new agents to improve hemodynamics, the effect of chronic ET receptor antagonism has not been beneficial in clinical heart failure trials, and use of such agents has led to worsening outcomes in some settings.¹¹

Neuropeptide Y. Neuropeptide Y (NPY) is a vasoconstricting peptide that is released together with NE from sympathetic nerve endings. NPY is abundant in cerebral cortex, hippocampus, thalamus, brainstem, and hypothalamus, where it is colocalized with agouti-related protein (AgRP), and positively modulates food intake. NPY is released from sympathetic nerves in the heart and influences coronary artery constriction and myocardial contraction. In addition, NPY potentiates the vasoconstrictor effects of other extracellular messengers, including α -adrenergic agonists and angiotensin II, and also inhibits acetylcholine release from parasympathetic nerve endings in the heart. Six NPY (NPY[1-6]) receptor subtypes have been identified thus far, of which NPY(1), NPY(2), and NPY(5) appear to be responsible for mediating functional responses in the heart.¹² Recent studies have suggested that NPY exerts important mitogenic and hypertrophic effects in endothelial and vascular smooth muscle cells, as well as cardiac myocytes. Although the role of NPY in heart failure is not known, circulating concentrations of NPY-like immunoreactivity are significantly increased in moderate to severe forms of heart failure and correlate with circulating levels of NE.¹²

Urotensin II. Mammalian urotensin II is the most potent endogenous cardiostimulatory peptide identified thus far, with a 8- to 110-fold greater potency than that of ET-1. The effects of urotensin II are mediated by binding to the urotensin receptor. Urotensin II mediates vascular tone and increased contractile force in human atrium and ventricle. Analogous to ET-1, urotensin II provokes trophic and/or mitogenic actions in vascular smooth muscle cells, cardiac myocytes, and cardiac fibroblasts. However, unlike ET-1, which uniformly constricts most blood vessels, the vasoactive effects of urotensin II are both species- and vascular bed-dependent. Urotensin receptor (GPR14) expression is increased in cardiac myocytes, endothelial cells, and fibroblasts in the rat heart after coronary artery ligation. Urotensin II treatment increased collagen mRNA and protein levels in cardiac fibroblasts and augmented cardiac hypertrophy in cultured neonatal cardiomyocytes after transfection with recombinant urotensin II receptor.¹³ Plasma levels of urotensin II have been found to be elevated in some but not all studies in patients with heart failure. Of interest, with iontophoresis of urotensin II into the skin, urotensin II mediated a dose-dependent vasodilator response in normal subjects but a dose-dependent vasoconstrictor response in patients with heart failure, suggesting that urotensin II may contribute to the increased peripheral vascular tone that occurs in heart failure.¹³

As noted previously, the vasoconstricting neurohormones activate counterregulatory vasodilator responses, including release of natriuretic peptides, NO, bradykinin, adrenomedullin, apelin, and vasodilating prostaglandins PGI₂ and PGE₂ (see [Table e22-1](#)). Under normal circumstances, the continuous release of NO (endothelium-derived

relaxing factor) from the endothelium counteracts the vasoconstricting factors and allows for appropriate vasodilatory responses during exercise. As heart failure advances, however, the endothelial cell-mediated vasodilatory responsiveness is lost, which contributes to the excessive peripheral arterial vasoconstriction that is emblematic of advanced heart failure. Of interest, the vasodilator response can be restored by the administration of L-arginine, a precursor of endothelium-derived NO (NO).

Nitric Oxide

The free radical gas NO is produced by three isoforms of NO synthase (NOS). All three isoforms are present in the heart, including NOS1 (neuronal NOS [nNOS]), NOS2 (inducible NOS [iNOS]) and NOS3 (so-called endothelial-constitutive NOS [eNOS]). NOS1 has been detected in cardiac conduction tissue, in intracardiac neurons, and in the SR of cardiac myocytes; NOS2 is an inducible isoform that is not normally expressed in the myocardium but is synthesized *de novo* in virtually all cells in the heart in response to inflammatory cytokines, whereas NOS3 is expressed in coronary endothelium and endocardium and in the sarcolemma and T-tubule membranes of cardiac myocytes. NOS1 and NOS3 can be activated by calcium or calmodulin, whereas the induction of NOS2 is calcium-independent. NO activates soluble guanylate cyclase (see [Fig. e22-2A](#)). Under normal circumstances, the continuous release of NO (endothelium-derived relaxing factor) from the endothelium counteracts the vasoconstricting factors and allows for appropriate vasodilatory responses during exercise. This activation leads to the production of cGMP, which in turn activates protein kinase G and cascade of different signaling events. In normal subjects, NO released by endothelial cells mediates vasodilation in the peripheral vasculature through cGMP mediated relaxation of vascular smooth muscle. In patients with heart failure, endothelium-dependent NO-mediated dilation of the peripheral vasculature is blunted, which has been attributed to decreased NOS3 expression and activity.

The actions of NO on the myocardium are complex and include both short-term alterations in function and energetics and longer-term effects on structure. NO modulates the activity of several key calcium channels involved in excitation-contraction coupling as well as mitochondrial respiratory complexes. This type of regulation is accomplished by spatial localization of different NOS isoforms in distinct cellular microdomains involved in excitation-contraction coupling. Specifically, NOS1 localizes to the SR in proximity to the ryanodine receptor (RyR) and the SR Ca²⁺ ATPase (SERCA2a), and NOS3 is found in sarcolemmal caveolae compartmentalized with cell surface receptors and the L-type Ca²⁺ channel ([Fig. e22-2B](#)). NO also participates in mitochondrial respiration, the process that fuels excitation-contraction coupling. The different NOS isoforms also may participate in the process of cardiac remodeling. LV remodeling was ameliorated and survival improved after myocardial infarction in transgenic mice deficient in NOS2.¹⁴ By contrast, overexpression of NOS3 resulted in improved remodeling after myocardial infarction. These contrasting effects of NOS2 and NOS3 may reflect the differences in amount of NO produced, which is much higher with NOS2. Emerging evidence points to an imbalance between increasing free radical production and decreased NO generation in heart failure, which has been termed the nitroso-redox imbalance.¹⁵ NOS uncoupling secondary to a deficiency of tetrahydrobiopterin may further contribute to the nitroso-redox imbalance.¹⁴ The nitroso-redox imbalance probably contributes to disease progression in heart failure secondary to increased oxidative stress, as well as loss of the peripheral vasodilatory effects of NO.

Bradykinin. Kinins are vasodilators that are released from inactive protein precursors (kininogens) through the action of proteolytic enzymes termed kallikreins. The biologic actions of the kinins are mediated by binding to B₁ and B₂ receptors. Most cardiovascular actions are initiated by the B₂ receptor, which is distributed widely in tissues, where it binds bradykinin and kallidin. The B₁ receptor binds the metabolites of bradykinin and kallidin. Stimulation of the B₂ receptor leads to vasodilation, which is mediated by the activation of NOS3, phospholipase A2, and adenylyl cyclase. Studies suggest that

FIGURE e22-2 A, Cellular actions in signaling of the natriuretic peptide system. Ang I = angiotensin I; AT₁R = angiotensin type 1 receptor; BK = bradykinin; GC = guanylate cyclase; GC = particulate guanylate cyclase S receptor; NEP = neutral endopeptidase; PDE = phosphodiesterase; PK = protein kinase; R_A = particulate guanylate cyclase A receptor; R_C = particulate guanylate cyclase C receptor. **B**, Interaction of oxidative and nitrosative pathways in heart failure. The principal sources of ROS in the cardiomyocyte are xanthine oxidoreductase (XOR), NADPH oxidase, and the mitochondria. NO is produced by nNOS1, situated in the SR and in the mitochondria, and by eNOS (situated in the caveolae in the cell membrane). XOR and NOS1 colocalize in the SR, and this allows the inhibition of XOR by NOS1, possibly through S-nitrosylation. In turn, XOR reduces S-nitrosoglutathione (GSNO), leading to the regeneration of glutathione (GSH), the enzyme that reduces SNO moieties in proteins and preserves the S-nitrosylation equilibrium. In SR, NOS 1 regulates the activity of the ryanodine receptor (RyR) through S-nitrosylation; by contrast, XOR-generated superoxide (O₂⁻) irreversibly activates RyR, precluding this regulatory action of NO. In the cell membrane, NOS3 suppresses NADPH activity, whereas NADPH-produced O₂⁻ can induce NOS3 uncoupling resulting in O₂⁻ production and reduced NO synthesis. O₂⁻ interacts with NO and generates peroxynitrite (ONOO⁻). Cyt = cytochrome; GSSG = oxidized GSH; GSNOR = GSNO reductase. (**A**, From Burnett JC, Costello-Boerrigter L, Boerrigter G: *Alterations in the kidney in heart failure: the cardiorenal axis in the regulation of sodium homeostasis*. In Mann DL [ed]: *Heart Failure: A Companion to Braunwald's Heart Disease*. Philadelphia, Elsevier, 2004, pp 279-289. **B**, From Tziomalos K, Hare JM: *Role of xanthine oxidoreductase in cardiac nitroso-redox imbalance*. *Front Biosci* 14:237, 2009.)

bradykinin plays an important role in the regulation of vascular tone in heart failure.¹⁶ The breakdown of bradykinin is catalyzed by ACE, so that this enzyme not only leads to the formation of a potent vasoconstrictor (angiotensin II) but also mediates the breakdown of a vasodilator (bradykinin). The augmentation of bradykinin levels likely contributes to the beneficial actions of ACE inhibitors (see Chapter 25).

Adrenomedullin. Adrenomedullin is a 52-amino-acid vasodilatory peptide that originally was discovered in human pheochromocytoma tissue. Subsequently, high levels of adrenomedullin immunoreactivity were detected in cardiac atrium and adrenal and pituitary glands, with lower levels detected in the ventricle, kidney, and vasculature.¹⁷ Adrenomedullin binds to a number of G protein–coupled receptors, including the calcitonin receptor-like receptor and one specific for the adrenomedullin peptide. Adrenomedullin receptors are present in multiple tissue beds, as well as both endothelial and vascular smooth muscle cells. Circulating concentrations of adrenomedullin are elevated in cardiovascular disease and heart failure in proportion to the severity of cardiac and hemodynamic impairment. Increasing evidence suggests that adrenomedullin may play a compensatory role in heart failure by offsetting the deleterious effects of excessive peripheral vasoconstriction. Plasma levels of adrenomedullin are elevated in chronic heart failure and are increased proportionally to disease severity. Immunoassays that detect the prohormone form of adrenomedullin have been shown to predict heart failure–related death in the BAC (Biomarkers in Acute Heart Failure) trial.¹⁸

Apelin. Apelin is a vasoactive peptide that is an endogenous ligand for the G protein–coupled receptor APJ. In the cardiovascular system, apelin elicits endothelium-dependent, NO-mediated vasorelaxation and reduces arterial blood pressure. In addition, apelin demonstrates potent and inotropic activity without stimulating concomitant cardiac myocyte hypertrophy. Apelin also produces diuresis by inhibition of arginine vasopressin activity. In experimental animals, apelin concentrations are significantly lower in failing hearts and are increased after treatment with an angiotensin receptor blocking agent. Furthermore, apelin levels are significantly reduced in patients with heart failure when compared with control subjects and are significantly increased after cardiac resynchronization. The cognate receptor for apelin, the APJ receptor, is bifunctional G protein receptor that conveys cytoprotective signals after endogenous ligand stimulation, and also acts as a mechanosensor to delimit cardiac hypertrophy following hemodynamic pressure overload.¹⁹

Adipokines. Although adipose tissue was once considered as a simple storage depot for fat, adipose tissue is now known to synthesize and secrete a family of proteins collectively referred to as *adipokines* (see Fig. e22-3). Adipokines include adiponectin, TNF, plasminogen activator inhibitor type 1 (PAI-1), transforming growth factor- β , and resistin. Leptin is a 16-kDa protein hormone that plays a key role in regulating energy intake and energy expenditure. Leptin, the product of the *ob* gene, is predominantly synthesized and secreted by adipocytes, although the heart is also a site of leptin synthesis. The initial role of leptin was thought to be decreasing appetite through hypothalamic stimulation and hence regulating food intake. However, elevated circulating levels of leptin, which act via a family of receptor (*ob.R*) isoforms, appear to play an important role in hypertension, hypertrophy, and heart failure.²⁰ Leptin may affect myocardial function through direct peripheral effects or through secondary central nervous system–mediated responses. Lack of leptin and/or leptin resistance may lead to an accumulation of lipids in nonadipose peripheral tissues, resulting in a variety of “lipotoxic” effects, including cardiac myocyte apoptosis. Several studies suggest that leptin directly induces hypertrophy in both human and rodent cardiac myocytes.²⁰

Adiponectin is a 224-amino-acid polypeptide that modulates a number of metabolic processes, including glucose regulation and fatty acid oxidation. Although adiponectin initially was thought to be exclusively produced by adipose tissue, recent studies have demonstrated adiponectin expression in the heart. Studies in adiponectin-deficient mice demonstrated progressive cardiac remodeling after hemodynamic pressure overloading, whereas administration of adiponectin diminished the infarct size, apoptosis, and TNF production after myocardial ischemia-reperfusion in both wild-type and adiponectin-deficient mice. Of interest, many studies have correlated decreased adiponectin levels with the development of obesity-linked heart failure. Thus adiponectin has been proposed as a potential biomarker of heart failure and as a potential therapeutic target in its treatment.²⁰

Inflammatory Mediators. One of the recent conceptual advances with respect to the current understanding of the pathogenesis of

heart failure has been the insight that the adult heart responds to tissue injury by synthesizing a series of proteins that promote homeostasis, either by activating mechanisms that facilitate tissue repair or, alternatively, by upregulating mechanisms that confer cytoprotective responses within the heart. An ensemble of proinflammatory cytokines including TNF, IL-1 β , and IL-6 serve as the downstream “effectors” of the innate immune system by facilitating tissue repair within the heart. What has been less well understood, until recently, is how these myocardial innate immune responses are coordinated after tissue injury. The relatively recent discovery of a family of receptors termed Toll-like receptors (TLRs) and NOD-like receptors (NLRs) has greatly increased our understanding of the “upstream” molecular components that regulate the innate immune response.²¹ Although the primary role for these molecules is to initiate repair of the injured myocardium, when expressed for protracted periods of time and/or when expressed at high levels, these molecules are sufficient to recapitulate virtually all aspects of the heart failure phenotype, by provoking deleterious changes in cardiac myocytes and nonmyocytes, as well as changes in the myocardial extracellular matrix (summarized in Table 22-1).²¹ Moreover, in experimental models, substantial cross-talk takes place between proinflammatory cytokines and RAS, such that angiotensin-II upregulates the expression of TNF through a nuclear factor κ -B (NF- κ B) dependent pathway, and the expression of inflammatory mediators leads to upregulation of RAS through increased activation of myocardial ACE and chymase. Circulating levels of proinflammatory cytokines including TNF and IL-6 are increased in patients with heart failure and correlate with adverse patient outcomes.²¹ Conversely, the plasma concentrations of anti-inflammatory cytokines such as IL-10 are reduced in patients with heart failure and are decreased more in direct relation to the severity of the degree of heart failure, suggesting that the imbalance between pro- and anti-inflammatory cytokine expression may contribute to progression of the disease process.

Left Ventricular Remodeling

Although the neurohormonal model explains many aspects of disease progression in the failing heart, increasing clinical evidence suggests that current neurohormonal models fail to completely explain the basis for this progression. That is, although neurohormonal antagonists stabilize and in some cases reverse certain aspects of the disease process in heart failure, in the overwhelming majority of patients, it will progress, albeit at a slower rate. It has been suggested that the process of LV remodeling is directly related to future deterioration in LV performance and a less favorable clinical course in patients with heart failure (a published review is available²²). LV remodeling is influenced by hemodynamic, neurohormonal, epigenetic,²³ and genetic factors (Fig. e22-4), as well as comorbid conditions. Although the complex changes that occur in the heart during LV remodeling have traditionally been described in anatomic terms,

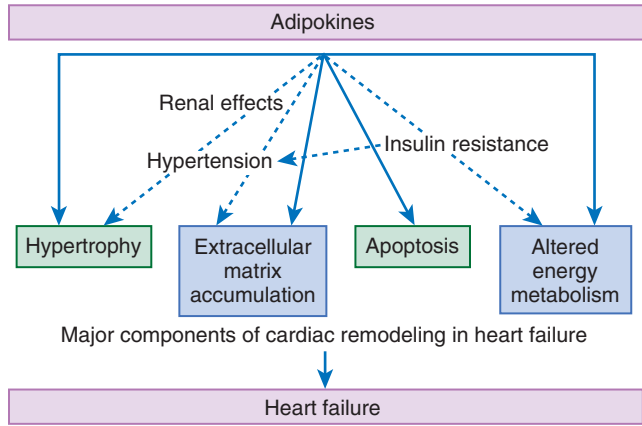

FIGURE e22-3 Potential direct and indirect effects of adipokines on cardiac remodeling. Various circulating adipokines, the profile of which alters in obesity, may directly (*solid lines*) influence remodeling events known to occur in heart failure: hypertrophy, apoptosis, fibrosis, and metabolic alterations. Another potential mechanism whereby adipokines may influence cardiac structure and function is through indirect effects (*broken lines*) on parameters known to influence cardiac remodeling, such as hypertension, insulin resistance, and renal effects. E = epinephrine. (From Abel ED, Litwin SE, Sweeney G: Cardiac remodeling in obesity. *Physiol Rev* 88:389, 2008.)

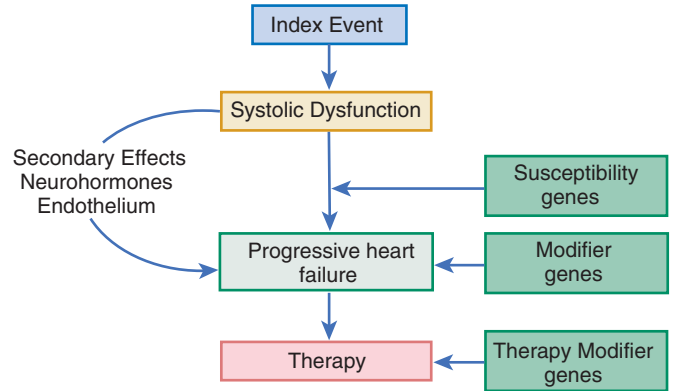

FIGURE e22-4 Role of genetics in the pathogenesis of heart failure. Gene polymorphisms may contribute to disease progression in heart failure through several mechanisms. Disease susceptibility genes may confer increased risk of disease progression after cardiac injury, whereas modifier genes can increase and/or decrease the impact of susceptibility genes. Finally, gene polymorphisms may modify the response to heart failure therapies (therapy modifier genes).

the process of LV remodeling also has an important impact on the biology of the cardiac myocyte, on changes in the volume of myocyte and nonmyocyte components of the myocardium, and on the geometry and architecture of the LV chamber (Table 22-2).

Alterations in the Biology of the Cardiac Myocyte

Numerous studies have suggested that failing human cardiac myocytes undergo a number of important changes that might be expected to lead to a progressive loss of contractile function, including decreased alpha-myosin heavy chain gene expression with a concomitant increase in beta-myosin heavy chain expression, progressive loss of myofilaments in cardiac myocytes, alterations in cytoskeletal proteins, and alterations in excitation-contraction coupling and in energy metabolism, as well as desensitization of beta-adrenergic signaling (see Table 22-2).

Cardiac Myocyte Hypertrophy

Two basic patterns of cardiac hypertrophy occur in response to hemodynamic overload (Fig. 22-8). In *pressure overload* hypertrophy (e.g., with aortic stenosis or hypertension), the increase in systolic wall stress leads to the addition of sarcomeres in parallel, an increase in myocyte cross-sectional area, and increased LV wall thickening. This pattern of remodeling has been referred to as “concentric” hypertrophy (see Fig. 22-8A), and has been linked with alterations in Ca^{2+} /calmodulin-dependent protein kinase II–dependent signaling²⁴ (Fig. 22-9). By contrast, in *volume overload* hypertrophy (e.g., with aortic and mitral regurgitation), increased diastolic wall stress leads an increase in myocyte length with the addition of sarcomeres in series, thereby engendering increased LV ventricular dilation). This pattern of remodeling has been referred to as “eccentric” hypertrophy (so named because of the position of the heart in the chest), or a “dilated” phenotype (see Fig. 22-8A), and has been linked with Akt activation (see Fig. 22-9).²⁴ Patients with heart failure classically present with a dilated left ventricle with or without LV wall thinning. The myocytes from these failing ventricles have an elongated appearance that is characteristic of myocytes obtained from hearts subjected to chronic volume overload.

Cardiac myocyte hypertrophy also leads to changes in the biologic phenotype of the myocyte that are secondary to reactivation of portfolios of genes normally not expressed postnatally. The reactivation of these fetal genes, the so-called fetal gene program, also is accompanied by decreased expression of an number of genes that are normally expressed in the adult heart. As discussed further on, activation of the fetal gene program may contribute to the

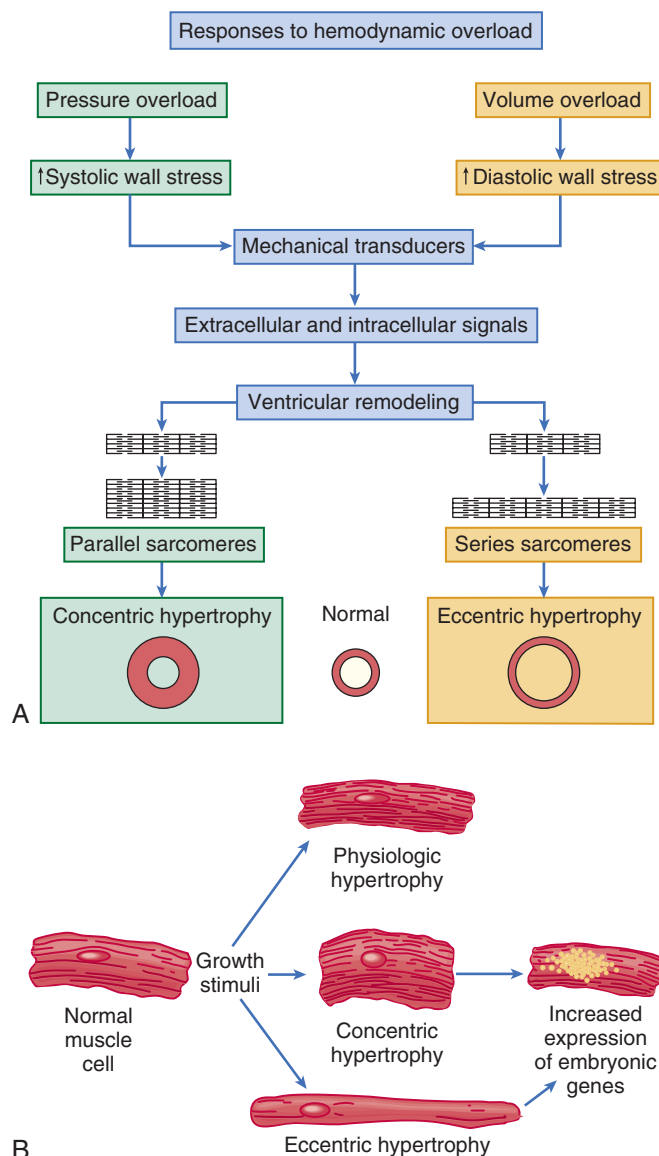

FIGURE 22-8 The pattern of cardiac and cellular remodeling that occurs in response to hemodynamic overloading depends on the nature of the inciting stimulus. **A**, When the overload is predominantly due to an increase in pressure (e.g., with systemic hypertension or aortic stenosis), the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes, resulting in concentric cardiac hypertrophy. When the overload is predominantly due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres, lengthening of cardiac myocytes, and LV dilation, which is referred to as eccentric chamber hypertrophy. **B**, Phenotypically distinct changes occur in the morphology of myocyte in response to the type of hemodynamic overload that is superimposed. When the overload is predominantly due to an increase in pressure the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes. When the hemodynamic overload is predominantly due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres with consequent lengthening of cardiac myocytes. The expression of maladaptive embryonic genes (see Table 22-2) is increased in both eccentric and concentric hypertrophy, but not in physiologic myocyte hypertrophy as occurs with exercise. (A, From Colucci WS [ed]: *Heart Failure: Cardiac Function and Dysfunction*. 2nd ed. Philadelphia, Current Medicine, 1999, p 4.2. B, Modified from Hunter JJ, Chien KR: *Signaling pathways for cardiac hypertrophy and failure*. *N Engl J Med* 341: 1276, 1999.)

contractile dysfunction that develops in the failing myocyte. As shown in Figure 22-9, the stimuli for the genetic reprogramming of the myocyte include mechanical stretch/strain of the myocyte, neurohormones (e.g., NE, angiotensin II), inflammatory cytokines (e.g., TNF, IL-6), other peptides and growth factors (e.g., ET), and ROS (e.g., superoxide, NO). These stimuli occur both locally within the

FIGURE 22-9 Cellular signaling pathways in cardiac myocyte hypertrophy. Many signaling pathways have the potential to regulate the growth of cardiac cells acting through an increasingly complex network of intracellular signaling cascades. Agonists for α -adrenergic, angiotensin, and ET receptors couple to phospholipase C (PLC) and calcium influx channels by way of G proteins. Activation of PLC results in the generation of two second messengers, inositol triphosphate (IP3) and diacylglycerol (DAG). IP3 causes the release of calcium from intracellular stores, and DAG activates protein kinase C (PKC). Changes in intracellular calcium stores can activate Ca^{2+} /calmodulin-dependent kinases (CaMK II), as well as calcineurin, which can affect gene expression in multiple ways. PKC and G proteins can affect gene expression by activating mitogen-activated protein kinase (MAPK) cascades. Histone deacetylase complexes (HDACs) are emerging as important negative regulators of genes involved in cardiac hypertrophy. Cytokines and peptide growth factors, such as insulin-like growth factor (IGF) can be elaborated by various cells within the heart and may act in an autocrine or paracrine manner. These growth factors activate cellular receptors that usually possess receptor tyrosine kinase (RTK) activity and are coupled to a cascade of protein kinase. Mechanical deformation of cardiac myocytes through matrix-integrin interactions can lead to activation or modulation of several signaling pathways, at least in part through autocrine action of released agonists such as angiotensin. Both NO and oxidative stress may be induced after stimulation of signaling pathways and modulate the activity of kinase cascades and transcription factors leading to alterations in contractile phenotype, growth, and death in myocytes. Akt = protein kinase B; C/EBP β = CCAAT/enhancer binding protein- β ; ER = endoplasmic reticulum; GATA4 = GATA-binding protein; gp130 = glycoprotein 130; GPCR = G protein-coupled receptor; HDAC = histone deacetylases; JAK = Janus kinase; MEF2 = myocyte enhancer factor; NFAT = nuclear factor of activated T cells; NF κ B = nuclear factor kappa B cells; NPR = natriuretic peptide receptor; P = phosphorylation; PDE5 = phosphodiesterase type 5; PGC1 α = peroxisome proliferator-activated receptor gamma, coactivator 1 alpha; PKA, PKD, PKG = protein kinases A, D, G; STAT = signal transducer and activator of transcription; SRF = serum response factor. (From Shah AM, Mann DL: *In search of new therapeutic targets and strategies for heart failure: Recent advances in basic science. Lancet* 378:704, 2011.)

myocardium, where they exert autocrine/paracrine effects, and systemically, where they exert endocrine effects.

The early stage of cardiac myocyte hypertrophy is characterized morphologically by increases in the number of myofibrils and mitochondria as well as enlargement of mitochondria and nuclei. At this stage, the cardiac myocytes are larger than normal, but with preservation of cellular organization. As hypertrophy continues, there is an increase in the number of mitochondria, as well as the addition of new contractile elements in localized areas of the cell. Cells subjected to longstanding hypertrophy show more obvious disruptions in cellular organization, such as markedly enlarged nuclei with highly lobulated membranes, accompanied by the displacement of adjacent myofibrils with loss of the normal registration of the Z-bands. The late stage of hypertrophy is characterized by loss of contractile elements (myocytolysis) with marked disruption of Z-bands and severe disruption of the normal parallel arrangement of the sarcomeres, accompanied by dilation and increased tortuosity of T tubules.

Alterations in Excitation-Contraction Coupling

As discussed in [Chapter 21](#), excitation-contraction coupling refers to the cascade of biological events that begins with the cardiac action potential and ends with myocyte contraction and relaxation (see

Fig. 21-1)). Impaired contraction and relaxation of the failing heart is most prominent at high heart rates, which results in a depressed force-frequency relationship. This has been demonstrated both in isolated strips of human myocardium and in clinical observations of patients ([Fig. 22-10](#)). Normally, higher contraction frequency increases cardiac performance because of a frequency-dependent augmentation of intracellular Ca^{2+} transients. By contrast, in the failing myocardium, a decline in force generation is seen with higher heart rates that is secondary to a decrease in amplitude of intracellular Ca^{2+} , a prolonged decline of the Ca^{2+} transient, and increased levels of diastolic calcium. The reduced intracellular Ca^{2+} transient is secondary to depletion of Ca^{2+} from the SR, which is the consequence of three major defects in calcium cycling that occur in the failing heart: (1) increased leak of calcium through RyRs; (2) impaired SR calcium uptake due to reduced SERCA2a (SR calcium pump) protein levels and function, and (3) increased expression and function of the sarcolemmal $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX).

Increased Ca^{2+} Leak

Calcium enters the cell during the action potential through L-type calcium channels and triggers a release of a far larger amount of calcium from the SR through RyRs. Although controversy exists

FIGURE 22-10 Relationship between contraction frequency and cardiac performance (force-frequency relation) in heart failure. **A**, Relationship between stimulation frequency and force generation of isolated muscle strip preparations from nonfailing and failing human hearts. In nonfailing myocardium contractile force increases up to a stimulation rate of approximately 2.5 Hz (150 beats/min), whereas contractile force does not significantly increase in failing myocardium. (* indicates $P < 0.05$ versus 0.25 Hz, # indicates $p < 0.05$ between failing and nonfailing myocardium.) **B**, Cardiac index versus heart rate in patients with and without heart failure. Heart rate was changed by temporary pacing during cardiac catheterization and cardiac output was measured by thermodilution. In patients without heart failure, cardiac index increases with higher heart rates up to 120 beats/min, but it declines continuously in patients with heart failure. (* indicates $P < 0.05$ and **, $P < 0.01$ versus lowest pacing rate.) DCM = dilated cardiomyopathy. (**A**, Modified from Pieske B, Maier LS, Bers DM, Hasenfuss G: Ca^{2+} handling and sarcoplasmic reticulum Ca^{2+} content in isolated failing and nonfailing human myocardium. *Circ Res* 85:38, 1999. **B**, Modified from Hasenfuss G, Holubarsch C, Hermann HP, et al: Influence of the force-frequency relationship on haemodynamics and left ventricular function in patients with non-failing hearts and in patients with dilated cardiomyopathy. *Eur Heart J* 15:164, 1994.)

regarding the expression levels of RyRs in heart failure, as well as the coupling of RyRs to L-type Ca^{2+} channels, there is general agreement that the diastolic Ca^{2+} leak in heart failure is the result of opening of RyRs during diastole. The resultant release of calcium from the SR event is referred to as a “ Ca^{2+} spark.” The pathophysiologic mechanism underlying the diastolic Ca^{2+} leak in heart failure has been attributed to increased phosphorylation of the RyR by protein kinase A (PKA), Ca^{2+} /calmodulin-dependent kinase (CaMKII), and/or from decreased binding of the RyR-stabilizing protein calstabin2 (FKBP12.6).^{25,26} Experimental studies suggest that PKA-dependent phosphorylation of the RyR may provoke Ca^{2+} leak by destabilizing the association between calstabin and RyRs (see also Chapter 21). Of interest, beta-adrenergic blocking agents prevent the development of heart failure in dogs by restoring RyR stabilization by FKBP12.6.²⁶ This latter observation has led to the suggestion that the increase in contractile function after treatment with beta-adrenergic blocking agents is secondary to RyR stabilization. The role of excess PKA-dependent RyR phosphorylation in the etiology of HF appears to be somewhat paradoxical, in that the β -receptor is downregulated in heart failure. One current proposal is for the presence of microdomains in close proximity to the RyR, where there is increased PKA phosphorylation and more cyclic AMP and decreased activity of the type 4 phosphodiesterase (PDE4D3).²⁷ Drugs with the ability to bind to and stabilize the RyR (referred to as RYCALs), such as the diltiazem derivative JTV 519, have been shown to attenuate experimental heart failure²⁶ and are currently being developed as novel therapeutic class drugs in the treatment of heart failure.

Sarcoplasmic Reticulum Ca^{2+} Reuptake and Sarcolemmal Ca^{2+} Elimination

Relaxation of the contractile proteins occurs after dissociation of Ca^{2+} from troponin C and Ca^{2+} elimination from the cytosol. In the human heart, there are two main mechanisms responsible for elimination of Ca^{2+} from the cytosol: (1) SR uptake of Ca^{2+} by the SERCA2a Ca^{2+} pump; and (2) transsarcolemmal Ca^{2+} elimination through Na^{+}/Ca^{2+} exchanger (NCX). Under normal conditions, up to 75% of Ca^{2+} is taken up by the SR and 25% of Ca^{2+} is extruded from the cell through

Na^{+}/Ca^{2+} exchanger. In heart failure there is decreased uptake of Ca^{2+} by the SR secondary to decreased SERCA2A protein levels and SERCA2A function. In addition, phosphorylation of phospholamban is reduced in the failing heart, resulting in increased phospholamban-dependent inhibition of the SR Ca^{2+} pump.²⁸ The decrease of SR Ca^{2+} uptake in the failing heart results in a relative increase of transsarcolemmal Ca^{2+} elimination by the NCX, which is most likely secondary to increased expression of NCX protein. Restoring deficient SERCA2a by gene transfer has been shown to improve contractile function and restores electric stability experimentally; this approach has shown to be safe and potentially beneficial in the CUPID (Calcium Upregulation by Percutaneous Administration of Gene Therapy in Cardiac Disease) trial (NCT00454818).²⁹ Although the increase in NCX activity may result in increased Ca^{2+} elimination from the myocyte, thereby preserving diastolic calcium levels and preventing diastolic dysfunction when SR calcium uptake is reduced, increased NCX activity may further reduce SR Ca^{2+} accumulation or content and may thereby reduce Ca^{2+} activation of contractile proteins.²⁸ Because the NCX is electrogenic (i.e., exchange of 3 Na^{+} versus 1 Ca^{2+} ion), NCX-induced elimination of Ca^{2+} is associated with a net inward current, which may lead to delayed afterdepolarizations and arrhythmias.

Action Potential Duration and Sodium Handling

Several factors contribute to the prolongation of the action potential duration, which is a ubiquitous finding in failing hearts.³⁰ The transient outward potassium current (I_{to}) and the inward rectifier potassium current (I_{K1}) both are reduced in heart failure. In addition, the increased inward Na^{+} current through the NCX and persistent activity of the sodium channel also may contribute to prolongation of the action potential. The latter mechanism, also termed the late sodium current, may be important in the pathogenesis of cardiac arrhythmias in heart failure. As discussed in Chapter 24, the voltage-gated Na^{+} channels are activated on depolarization of the cell membrane, leading to rapid influx of Na^{+} that is responsible for the fast upstroke of the action potential (see Fig. e22-5B). Under normal conditions, Na^{+} channels inactivate a few milliseconds after depolarization. However, it is now recognized that some Na^{+} channels remain open (or reopen), leading to a small but persistent influx of Na^{+} throughout the plateau of the action potential, which generates a “late” sodium current (I_{Na}).³¹ Although the amplitude of late I_{Na} is small compared with peak I_{Na} , the current is sufficient to lead to a substantial influx of Na^{+} into the cell in heart failure, with consequent prolongation of the action potential and early afterdepolarizations, which may be a significant source of increased arrhythmias in heart failure.³² High levels of intracellular Na^{+} also may lead to cellular acidosis secondary to increased sodium-proton exchange activity. Increased intracellular Na^{+} also influences the driving forces for the NCX, thereby reducing Ca^{2+} extrusion through the forward mode of the NCX, which when combined with reduced activity of the SERCA2a pump may be a cause of the elevated diastolic cytosolic calcium levels and disturbed diastolic function in heart failure. Inhibition of the late Na^{+} current with the inhibitor ranolazine can improve disturbed diastolic function in isolated myocardium from failing human hearts and also may exhibit antiarrhythmic properties.³³ Of note, the different contributions to altered Ca^{2+} handling may vary significantly from patient to patient, which may explain the heterogeneity of different heart failure phenotypes. If SERCA2a expression is decreased and intracellular sodium is high, both systolic and diastolic function will be impaired. By contrast, higher NCX expression with moderately elevated intracellular Na^{+} will result in excess transsarcolemmal calcium elimination, and diastolic function will be rather preserved. However, this may be associated with increased arrhythmias secondary to increased NCX activity.²⁸

Abnormalities in Contractile and Regulatory Proteins

Early studies showed that the activity of myofibrillar ATPase was reduced in the hearts of patients who died of heart failure. Furthermore, reductions in the activities of myofibrillar ATPase, actomyosin ATPase, or myosin ATPase have been demonstrated in several animal models of heart failure. Subsequent studies showed that these

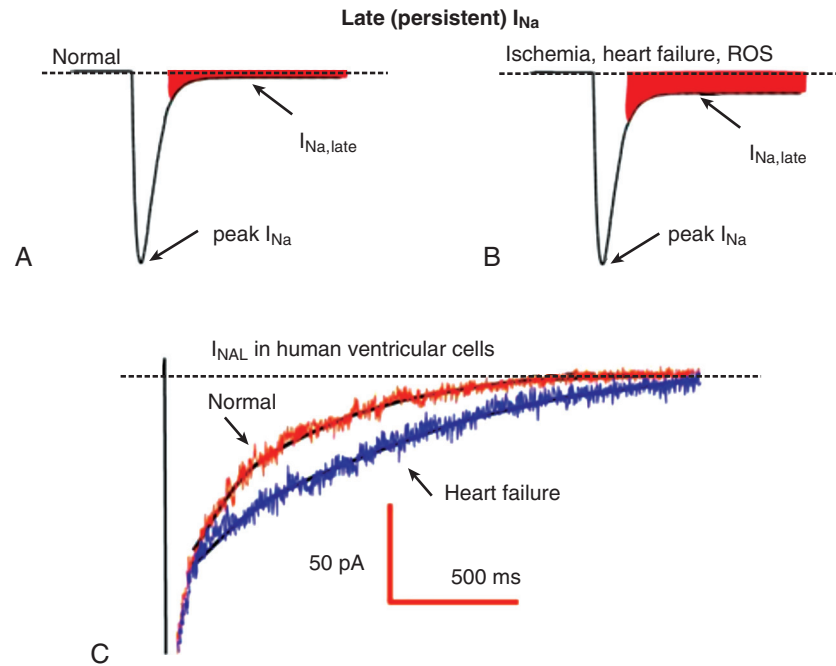

FIGURE e22-5 Sodium current under normal and disease conditions. **A**, Cartoon of Na^+ current in nonfailing myocardium. Under normal conditions, Na^+ channels inactivate a few milliseconds after depolarization and net Na^+ influx is small. **B**, Pathologic conditions (ischemia, heart failure, ROS) alter Na^+ current. Channels remain open (or reopen), and a persistent influx of Na^+ generates the so-called late Na^+ current ($I_{Na,late}$). This causes a substantial influx of Na^+ , which contributes to elevated Na^+ concentrations under conditions of heart failure. **C**, Original recordings of Na^+ currents from human ventricular isolated cells. Persistent opening of Na^+ channels in the myocyte from a failing heart results in a larger Na^+ influx relative to that for the myocyte from the normal heart (From Maltsev VA, Silverman N, Sabbah HN, et al: *Eur J Heart Fail* 9:219, 2007.)

abnormalities in ATPase activity could be explained by a shift to the fetal isoform of myosin heavy chain (MHC) in cardiac hypertrophy and failure. In rodents, the predominant MHC is the “fast” V1 isoform (alpha-MHC [MYHC6]), which has high ATPase activity. With pressure-induced hypertrophy or after myocardial infarction in rodents, reexpression of the “slow” V3 fetal isoform of MHC that has low ATPase activity (beta-MHC [MYHC7]) and decreased expression of the V1 isoform have been observed. Although translating this information to human heart failure proved to be more challenging, insofar as the predominant MHC isoform in humans is the slower V3 isoform (MYHC7), with the development of polymerase chain reaction (PCR) techniques, it has been possible to demonstrate that the MYHC6 accounts for approximately 33% of MHC mRNA in normal human myocardium, whereas MYHC6 mRNA abundance decreases to approximately 2% in failing hearts. Furthermore, in human studies in which myocardial biopsy was performed in patients receiving beta blocking agents, reciprocal changes were observed in the levels of MYHC6 (increase) and MYHC7 (decrease) mRNA, and an increase in the ratio of MYHC6/MYHC7 was noted in the patients who demonstrated an improvement in LV function, whereas these changes in myosin isoform shifts did not occur in patients with heart failure in whom no improvement in LV function was achieved with beta blocking agent therapy (Fig. e22-6). Thus the decreased expression of MYHC6 may play a significant role in the pathophysiology of dilated cardiomyopathy. Another important modification of contractile proteins that contributes to contractile dysfunction is proteolysis of the myofilaments themselves (myocytolysis). Myocardial biopsy samples from patients with advanced LV dysfunction show a significant reduction in the volume of myofibrils per cell, which may contribute to the development of cardiac decompensation.

Alterations in the expression or activity, or both, of myofilament regulatory proteins also have been proposed as a potential mechanism for the decrease in cardiac contractile function in heart failure (Table 22-3), including in the myosin light chains, the troponin-tropomyosin complex, and titin. Changes in myosin light chain isoforms have been observed in the atria and ventricles of patients whose hearts have been subjected to mechanical overload. Although changes in the abundance and/or isoforms of troponins TnT and TnC (see also Chapter 21) have not been reported in heart failure, isoform shifts have been reported in TnT. In normal adult myocardium, TnT is expressed as a single isoform (cTnT3). However, in myocardium samples from patients with end-stage heart failure, both the fetal cTnT1 and the cTnT4 isoforms are expressed at increased levels, which might be expected to lead to a decrease in maximal active tension. Changes in the titin isoform from the N2B isoform, which is expressed postnatally and is stiffer, to the N2BA more distensible fetal isoform, have been associated with increased compliance in hearts from patients with heart failure.³⁴

Abnormalities in Cytoskeletal Proteins

The cytoskeleton of cardiac myocytes consists of actin, the intermediate filament desmin, the sarcomeric protein titin (see Chapter 21), and alpha- and beta-tubulin, which form the microtubules by polymerization. Vinculin, talin, dystrophin, and spectrin constitute a separate group of membrane-associated proteins. In numerous experimental studies, a role for cytoskeletal and/or membrane-associated proteins has been implicated in the pathogenesis of heart failure. In patients with dilated cardiomyopathy, titin is downregulated and the cytoskeletal proteins desmin and membrane-associated proteins such as vinculin and dystrophin are upregulated. Proteolytic digestion of the dystrophin molecule has been identified as a possible reversible cause of heart failure.³⁵ Loss of integrity of the cytoskeleton and its linkage of the sarcomere to the sarcolemma and extracellular matrix would be expected to lead to contractile dysfunction at the myocyte level, as well as at the myocardial level.

Beta-Adrenergic Desensitization

Ventricles obtained from patients with heart failure demonstrate a marked reduction in beta-adrenergic receptor density, isoproterenol-mediated adenyl cyclase stimulation, and the contractile response to

beta-adrenergic agonists.³⁶ The downregulation of beta-adrenergic receptors probably is mediated by increased levels of NE in the vicinity of the receptor (see Fig. e22-6). In patients with dilated cardiomyopathy, this reduction in receptor density involves primarily the beta₁-receptor protein and mRNA and is proportional to the severity of heart failure. By contrast, the level of beta₂-adrenergic receptor protein and mRNA are unchanged. In addition, there are increases in the expression of beta-adrenergic receptor kinase 1 (βARK1), also called G protein-coupled receptor kinase 2 (GRK2), a member of the family of G protein-coupled receptor kinases, in failing human hearts. As noted in Chapter 21, βARK phosphorylates the cytoplasmic loops of both beta₁- and beta₂-adrenergic receptors and increases the affinity of these receptors for a scaffolding protein termed beta-arrestin (see Fig. 21-15). The binding of beta-arrestins to the cytoplasmic tail of the beta receptor not only uncouples the receptor from heterotrimeric G proteins but also targets the receptor for internalization in clathrin-coated vesicles. Although this internalization fosters receptor dephosphorylation and serves as a prelude to recycling the beta-receptor to the surface for reactivation, at some point receptor entry via endocytosis is not followed by recycling but rather leads to receptor trafficking to lysosomes and receptor degradation. Increased βARK activity may therefore contribute to the desensitization of both beta₁- and beta₂-adrenergic receptors in patients with heart failure. Desensitization of the beta receptors can be both beneficial and deleterious in heart failure. By reducing LV contractility,

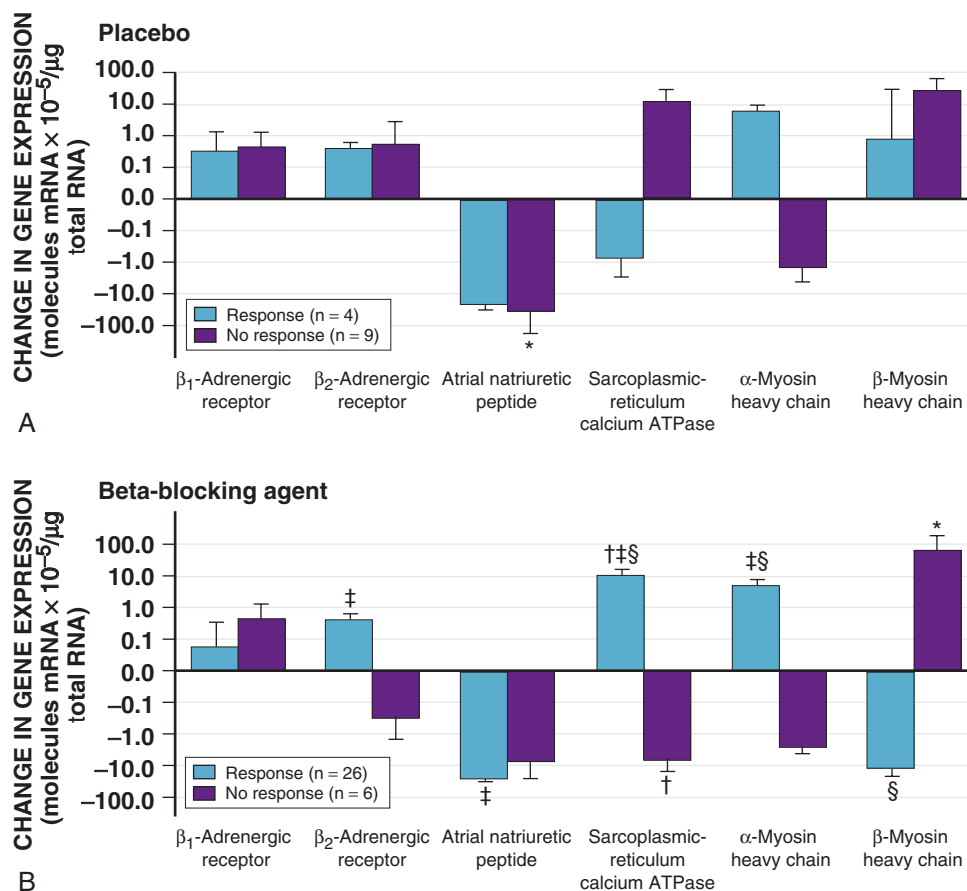

FIGURE e22-6 Changes in myocardial mRNA expression and beta-adrenergic receptor protein levels. **A, B**, Changes between baseline and the end of the 6-month study in the abundance of myocardial mRNA for six contractility-regulating or hypertrophy-regulating proteins in patients who received either placebo or a beta blocking agent. The changes in patients who had an improvement in LV ejection fraction (a "response," defined as an increase by at least 5 ejection fraction [EF] units) were compared with the changes in patients who did not demonstrate such a response. Gene expression is shown as molecules of mRNA per microgram of total RNA on a logarithmic scale. The *asterisk* indicates $P < .10$ for the change between the baseline value and the value measured at 6 months by the paired t -test; †, $P < .05$ for the comparison with the placebo group by the test for interaction; ‡, $P < .05$ for the change between the baseline value and the value measured at 6 months by the paired t -test; and §, $P < .05$ for the comparison with patients who did not have a response. Each panel shows results for patients with complete data for the indicated mRNA and receptor protein measurements. (From Lowes BD, Gilbert EM, Abraham WT, et al: Myocardial gene expression in dilated cardiomyopathy treated with beta blocking agents. *N Engl J Med* 346:1357, 2002.)

desensitization may be deleterious; however, by reducing energy expenditure of the energy-starved myocardium and protecting the myocyte from the deleterious effects of sustained adrenergic stimulation, this adaptive response is beneficial. Of interest, transgenic mice that overexpress β ARK are protected from developing heart failure.³⁷

Alterations in the Myocardium

The alterations that occur in failing myocardium may be categorized broadly into those that occur in the volume of cardiac myocytes, as well as changes that occur in the volume and composition of the extracellular matrix. With respect to the changes that occur in cardiac myocyte component of the myocardium, increasing evidence suggests that progressive myocyte loss, through necrotic, apoptotic, or autophagic cell death pathways, may contribute to progressive cardiac dysfunction and LV remodeling. Myocardial regeneration is discussed in [Chapter 30](#).

Necrosis. Although necrosis initially was thought to be a “passive” form of cell death, emerging evidence indicates that necrotic cell death also is “regulated.”³⁸ The relative proportion of unregulated versus regulated necrotic death in the heart is not currently known; however, regulated necrosis is an important component of myocardial infarction, heart failure, and stroke. The hallmark features of necrosis are loss of plasma membrane integrity and depletion of cellular adenosine triphosphate (ATP). Dysfunction of the plasma membrane in necrotic cells leads to cell swelling and rupture. There is also swelling of organelles such as the mitochondria. In the heart, increased plasma membrane permeability allows calcium to leak into the cell, exposing the contractile proteins to very high concentrations of this activator, which in turn initiates extreme interactions between the myofilaments (contraction bands), further contributing to disruption of the cellular membrane. Necrotic myocyte death occurs in ischemic heart disease, myocardial injury, toxin exposure (e.g., daunorubicin—see [Chapter 69](#)), infection, and inflammation. Neurohormonal activation also can lead to necrotic cell death. For example, concentrations of NE available within myocardial tissue, as well as circulating levels in patients with advanced heart failure, are sufficient to provoke myocyte necrosis in experimental model systems. Moreover, excessive stimulation with either angiotensin II, ET, or TNF has been shown to provoke myocyte necrosis in experimental models. In contrast with apoptosis (discussed next), the rupture of cell membranes with cell necrosis releases intracellular contents, so-called DAMPS (danger-associated molecular patterns), which evoke an intense inflammatory reaction, leading to the influx of granulocytes, macrophages, and collagen-secreting fibroblasts into the area of injury. The final result is a fibrotic scar, which may alter the structural and functional properties of the myocardium (see later on). The regulated cell death pathways that have been studied thus far include TNF signaling through the type 1 TNF receptor (TNFR1) and opening of the mitochondrial permeability transition pore (MPTP) in the inner mitochondrial membrane, resulting in loss of the electrical potential difference ($\Delta\psi$ m) across the inner mitochondrial membrane, leading to ATP depletion ([Fig. 22-11A](#)).

Apoptosis. Apoptosis, or programmed cell death, is an evolutionarily conserved process that allows multicellular organisms to selectively remove cells through a highly regulated program of cell suicide. Apoptosis is mediated by two pathways ([Fig. 22-11B](#)). The extrinsic pathway utilizes cell surface receptors, whereas the intrinsic pathway involves the mitochondria and endoplasmic reticulum (ER), and each of these pathways leads to caspase activation. In addition, connections between the pathways amplify signals, increasing the efficiency of killing. The intrinsic pathway is responsible for transducing most apoptotic stimuli, including those due to inadequate nutrients or survival factors, hypoxia, oxidative stress, nutrient stress, proteotoxic stress, DNA damage, and chemical and physical toxins. These stimuli ultimately converge at the mitochondria to trigger the release of apoptogenic proteins, such as cytochrome c, and at the ER to stimulate the release of luminal Ca^{2+} .³⁸ Apoptosis plays important roles in development and in postnatal life, when it is critical for tissue homeostasis and surveillance for damaged or transformed cells. However, under pathologic circumstances, such as acute ischemia and/or in dilated cardiomyopathy, the apoptotic program can be triggered inappropriately, resulting in inadvertent cell death that can lead to organ failure. In contrast with the cell swelling that characterizes necrosis, during apoptosis the cell shrinks and eventually breaks up into small, membrane-surrounded fragments. The latter often contain bits of condensed chromatin referred to as apoptotic bodies. Maintenance

of plasma membrane integrity until late in the apoptotic process allows the dying cell to be engulfed by macrophages, which prevents the release of the reactive intracellular contents, thereby preventing an inflammatory reaction.

Cardiac myocyte apoptosis has been shown to occur in failing human hearts.³⁹ Indeed, many of the factors that have been implicated in the pathogenesis of heart failure, including catecholamines acting through β -adrenergic receptor, angiotensin II, ROS including NO, inflammatory cytokines (e.g., TNF), and mechanical strain, have been shown to trigger apoptosis *in vitro*. Moreover, activation of either the extrinsic or intrinsic cell death pathways provokes progressive LV dilation and decompensation in transgenic mice.⁴⁰ Nonetheless, the exact physiologic significance and consequence(s) of apoptosis in human heart failure has been difficult to determine because of the tremendous uncertainty with respect to the actual rate of cardiac myocyte apoptosis in the failing human heart.³⁹ This statement notwithstanding, the aggregate clinical and experimental data suggest that apoptosis is likely to play an important role in heart failure.

Autophagy. *Autophagy* refers to the homeostatic cellular process of sequestering organelles, proteins, and lipids in a double-membrane vesicle inside the cell (autophagosome), where the contents are subsequently delivered to the lysosome for degradation. In contrast with necrosis and apoptosis, autophagy is primarily a survival mechanism that regulates the quality and abundance of intracellular proteins and organelles. The three types of autophagy are macroautophagy, microautophagy, and chaperone-mediated autophagy. The term *autophagy* generally refers to macroautophagy unless otherwise specified. When autophagy involves the total destruction of the cell, it is referred to as *autophagic cell death*.

Recent studies have demonstrated the existence of autophagic cell death in hypertrophied, failing, and hibernating myocardium.³⁸ Approximately 0.3% of the cardiac myocytes in explanted hearts from patients with heart failure exhibited autophagic cell death,⁴¹ whereas the predominant form of cell death in pressure overloaded human hearts was mainly by autophagy and oncosis.⁴² Recent studies, however, have clearly demonstrated that autophagy has a variety of physiologic roles in the heart, and that impaired clearance of autophagosomes (impaired autophagic flux) may be deleterious, rather than the process of autophagy per se.⁴³

Although the distinction between necrosis and apoptosis is obvious in certain circumstances, the dividing line between these two conditions often is less clear in the failing heart. Indeed, similar mechanisms can operate in both types of cell death. Thus, instead of the existence of distinct types of cell death in heart failure, a more likely scenario is a continuum of cell death responses that contribute to progressive myocyte loss and disease progression.

Changes within the extracellular matrix (ECM) constitute the second important myocardial adaptation that occurs during cardiac remodeling. The myocardial ECM consists of a basement membrane, a fibrillar collagen network that surrounds the myocytes, proteoglycans and glycosaminoglycans, and specialized proteins such as matricellular proteins. The major fibrillar collagens in the heart are type I and III, with a ratio of type I to type III of approximately 1.3 to 1.9:1. The organization of myocardial fibrillar type I and type III collagen ensures the structural integrity of adjoining myocytes and is essential for maintaining alignment of myofibrils within the myocyte through the interaction of collagen and integrins and the cytoskeletal proteins ([Fig. 22-12A](#)). Matricellular proteins are a class of nonstructural ECM proteins exerting regulatory functions, most likely through their interactions with cell surface receptors, the structural proteins, and soluble extracellular factors such as growth factors and cytokines. Osteopontin (OPN [Eta-1]) is a matricellular protein that is expressed in various cell types, including cardiac myocytes and fibroblasts. Because of its localization and molecular properties, OPN is likely to be involved in the communication between the ECM and cardiac myocytes, which implies a role in cardiac remodeling after hemodynamic overloading. OPN is markedly upregulated in animal models of cardiac hypertrophy and failure and/or in myocardial ischemia and in the hearts of patients with dilated cardiomyopathy and is elevated in the peripheral circulation of patients in direct relation to heart failure disease severity.⁴⁴

Necrosis

A

Apoptosis

B

FIGURE 22-11 Apoptotic and necrotic cell death pathways. **A**, Necrosis. Information about regulated signaling in necrosis is currently limited to two pathways. The first involves death receptors, as exemplified by TNFR1 (tumor necrosis factor- α receptor 1). Depending on context, activation of TNFR1 can promote cell survival or either apoptotic or necrotic cell death. These choices are mediated by multiprotein complexes I and II. The binding of TNF- α to TNFR1 stimulates formation of complex I, which contains TNFR1, TRADD, RIP1, TRAF2, and cIAP1/2. Death effects of TNFR1 signaling are mediated via complex II, which forms after endocytosis of complex I, the dissociation of TNFR1, and the deubiquitination of RIP1 by CYLD and A20 (not shown). A second necrosis pathway involves the mitochondrial permeability transition pore (MPTP) in the inner mitochondrial membrane and its regulation by cyclophilin D (CypD). This pore may be opened by increased Ca^{2+} , oxidative stress, decreased ATP generation, and other stimuli that operate during ischemia-reperfusion and heart failure. Ischemia-reperfusion can lead to increased Ca^{2+} and ROS, as depicted. MPTP opening results in profound alterations in mitochondrial structure and function, which results in decreased ATP generation. **B**, Apoptosis is mediated by an extrinsic pathway involving cell surface death receptors and by an intrinsic pathway that uses the mitochondria and ER. The extrinsic pathway is activated by binding of death ligand to its receptor, which triggers formation of the DISC (death-inducing signaling complex). Caspase-8 is activated by forced proximity within the DISC and then cleaves and activates downstream procaspases. Caspase-8 also can cleave the BH3-only protein Bid, which translocates to the mitochondria to trigger apoptotic mitochondrial events. The intrinsic pathway is activated by diverse biologic, chemical, and physical stimuli. These signals are transduced to the mitochondria and ER (not shown) by proapoptotic Bcl-2 proteins: Bax (a multidomain protein) and BH3-only proteins. These death signals trigger the release of apoptogens from the mitochondria into the cytosol, including cytochrome c, which triggers the formation of a second multiprotein complex, the apoptosome, in which procaspase-9 undergoes activation. Caspase-9 then cleaves and activates downstream procaspases. Downstream caspases cleave several hundred cellular proteins to bring about the apoptotic death of the cell. cIAP1/2 = cellular inhibitor of apoptosis; FADD = Fas-associated protein with death domain; RIP1, RIP3 = receptor-interacting proteins 1, 3; TRADD = tumor necrosis factor receptor type 1-associated death domain protein; TRAF2 = TNF receptor-associated factor. (Modified from Whelan RS, Kaplinsky V, Kitsis RN: Cell death in the pathogenesis of heart disease: Mechanisms and significance. *Annu Rev Physiol* 72:19, 2010.)

FIGURE 22-12 Extracellular matrix in heart failure. **A**, Although myocytes are the major components of heart on the basis of mass, they represent only a minority on the basis of number. Nonmyocyte cellular constituents of the myocardium include fibroblasts, smooth muscle cells, and endothelial cells. Myocytes and nonmyocytes are interconnected by a complex of connective tissue and extracellular matrix. Components of the extracellular matrix include collagens, proteoglycans, glycoproteins (such as fibronectin), several peptide growth factors, and proteases (such as plasminogen activators) and collagenases (such as MMPs). **B**, Interactions among cardiac fibroblasts, myocytes, and the extracellular matrix. In response to biomechanical stress, peptide growth factors in the extracellular matrix and adjacent cardiac fibroblasts release an ensemble of peptide growth factors that activate hypertrophic signaling pathways in cardiac myocytes. (**A**, Modified from Weber KT, Brilla CG: Pathological hypertrophy and cardiac interstitium. *Circulation* 83:1849, 1991. **B**, Modified from Kakkar R, Lee RT: Intramyocardial fibroblast myocyte communication. *Circ Res* 106: 47, 2010.)

During cardiac remodeling there are important changes in the ECM, including changes in fibrillar collagen synthesis and degradation (**Fig. 22-13**) and in the degree of collagen cross-linking, as well as loss of collagen struts that connect the individual cardiac myocytes.⁴⁵ Markers of collagen turnover have been shown to be increased in patients with dilated cardiomyopathy compared with age-matched control subjects.⁴⁵ In patients with idiopathic or ischemic dilated cardiomyopathy, serum N-terminal type III collagen peptide (PIIINP) levels have been shown to be independent predictors of mortality.⁴⁶ In the RALES trial (see **Chapter 25**), serum PIP and PIIINP were decreased in the spironolactone-treated patients but not in the placebo group, suggesting that aldosterone may play an important role in ECM synthesis. Moreover, it is becoming increasingly apparent that the three-dimensional organization of the extracellular matrix plays an important role in regulating cardiac structure and function in heart failure.⁴⁷

Cardiac Fibroblasts and Mast Cells. The cardiac fibroblast, which accounts for almost 90% of nonmyocyte cells in the heart, is the primary cell type that is responsible for the secretion of a majority of ECM components in the heart, such as collagens I, III, and IV and laminin and fibronectin. In response to mechanical stress and/or neurohormonal activation, a subset of fibroblasts undergoes phenotypic conversion to myofibroblasts that are characterized by increased expression of α -smooth muscle actin and enhanced secretory activity. Myofibroblasts migrate into the area surrounding tissue injury where they are responsible for the collagen secretion and contraction/realignment of the nascent collagen fibers, and thus play an important role in the final scar formation at the site of injury. Cardiac fibroblasts also may regulate the phenotype of cardiac myocytes through paracrine signaling pathways (see **Fig. 22-12B**). Several lines of evidence suggest that cardiac fibroblasts and myocytes release proteins that regulate neighboring cells.⁴⁸ The proteins that have been implicated thus far include transforming growth factor- β 1 (TGF- β 1), fibroblast growth factor-2 (FGF2), members of the IL-6 family, and the recently discovered cytokine IL-33. Finally, increasing evidence suggests that mast cells, which are bone marrow-derived cells that “home” to and reside in the myocardium, also play an important role in remodeling of the ECM. Myocardial mast cells are located mainly around blood

vessels and between myocytes, where they are capable of releasing profibrotic cytokines and growth factors that influence ECM remodeling. In experimental studies, mast cells that are recruited to the heart during inflammation were responsible for TGF- β 1-mediated fibroblast activation, myocardial fibrosis, and LV diastolic dysfunction.⁴⁹

As noted earlier, one of the histologic signatures of advancing heart failure is the progressive increase in collagen content of the heart (myocardial fibrosis). Studies in failing human myocardium have shown a quantitative increase in collagen types I, III, VI, and IV along with fibronectin, laminin, and vimentin and a decrease in the ratio of type I collagen to type III collagen in patients with ischemic cardiomyopathy. Moreover, clinical studies point to a progressive loss of cross-linking of collagen in the failing heart, as well as loss of connectivity of the collagen network with individual myocytes, which would be expected to result in profound alterations in LV structure and function. Furthermore, loss of cross-linking of the fibrillar collagen has been associated with progressive LV dilation after myocardial injury. The accumulation of collagen can occur on a “reactive” basis around intramural coronary arteries and arterioles (perivascular fibrosis) or in the interstitial space (interstitial fibrosis) and does not require myocyte cell death (**Fig. e22-7**). Alternatively, collagen accumulation can occur as a result of microscopic scarring (replacement fibrosis), that develops in response to cardiac myocyte cell necrosis. This scarring or “replacement fibrosis” is an adaptation to the loss of parenchyma and is therefore critical to preserve the structural integrity of the heart. The increased fibrous tissue would be expected to lead to increased myocardial stiffness, which presumably would result in decreased myocardial shortening for a given degree of afterload. In addition, myocardial fibrosis may provide the structural substrate for atrial and ventricular arrhythmias, thus potentially contributing to sudden death (see **Chapter 39**). Although the full complement of molecules responsible for fibroblast activation is not known, many of the classical neurohormones (e.g., angiotensin II, aldosterone) and cytokines (ET, transforming growth factor- β [TGF- β], cardiotrophin-1) that are expressed in heart failure are sufficient to provoke fibroblast activation. Indeed, the use of ACE inhibitors, beta blocking agents, and aldosterone receptor antagonists has been associated with a decrease in myocardial fibrosis in experimental heart failure models.⁶

Although the fibrillar collagen matrix initially was considered to form a relatively static complex, it is now recognized that these

FIGURE e22-7 Myocardial fibrosis. Histologic section of a human myocardial biopsy specimen showing interstitial (**A**) and perivascular (**B**) fibrosis using picrosirius red staining. (Modified from Lopez B, Gonzales A, Varo N, et al: *Biochemical assessment of myocardial fibrosis in hypertensive heart disease. Hypertension* 38:1222, 2001.)

FIGURE 22-13 Collagen synthesis and degradation. **A**, Intracellular signals generated by neurohormonal and/or mechanical stimulation of cardiac fibroblasts results in transcription and translation of nascent collagen proteins containing aminoterminal (N-terminal) and carboxylterminal (C-terminal) propeptides that prevent collagen from assembling into mature fibrils. Once secreted into the interstitium, these propeptides are cleaved by N- and C-proteinases, yielding two procollagen fragments and a mature triple-stranded collagen molecule. In the case of collagen type I, these propeptides are referred to as N-terminal peptide collagen type I propeptide (PINP) and C-terminal peptide type I collagen propeptide (PIP). Removal of the propeptide sequences allows the secreted collagen molecule to integrate into growing collagen fibrils which can then further assemble into collagen fibers. After the collagen fibrils form in the extracellular space, their tensile strength is greatly strengthened by the formation of covalent cross-links between the lysine residues on the collagen molecules. **B**, The degradation of the collagen matrix within the myocardium entails a number of biochemical events involving a number of protease systems. Degradation of collagen fibrils occurs through catalytic cleavage of the three collagen α chains at a single locus by interstitial collagenase, yielding 36-kDa and 12-kDa collagen telopeptides that maintain their helical structure and thus are resistant to further proteolytic degradation. The big 36-kDa telopeptide spontaneously denatures into nonhelical gelatin derivatives, which in turn are completely degraded by interstitial gelatinases. The small 12-kDa pyridinoline cross-linked C-terminal telopeptide resulting from the cleavage of collagen type I (ICTP) is found in intact in blood, where it appears to be derived from tissues, with a stoichiometric ratio of 1:1 between the number of collagen type I molecules degraded and that of ICTP released. (From Deschamps AM, Spinale FG: *Extracellular matrix*. In Walsh RA [ed]: *Molecular Mechanisms of Cardiac Hypertrophy and Failure*. Boca Raton, Fla, Taylor & Francis, 2005, pp 101-116.)

structural proteins can undergo rapid turnover. One of the more exciting developments with respect to understanding the pathogenesis of cardiac remodeling has been the discovery that a family of collagenolytic enzymes, collectively referred to as *matrix metalloproteinases* (MMPs), are activated within the failing myocardium. Conceptually, disruption of the extracellular matrix would be expected to lead to LV dilation and wall thinning as a result of mural realignment ("slippage") of myocyte bundles and/or individual myocytes within the LV wall (as depicted in [Fig. e22-8](#)), as well as LV dysfunction as a result of dysynchronous contraction of the left ventricle. Although the precise biochemical triggers that are responsible for activation of MMPs are not known, it bears emphasis that TNF and other cytokines and peptide growth factors that are expressed within the failing myocardium are capable of activating MMPs. However, the biology of matrix remodeling in heart failure is likely to be much more complex than the simple presence or absence of MMP activation, insofar as degradation of the matrix also is controlled by glycoproteins, termed *tissue inhibitors of matrix metalloproteinases* (TIMPs), that are capable of regulating the activation of MMPs by binding to and preventing these enzymes from degrading the collagen matrix of the heart. The TIMP family at present consists of four distinct members, TIMP-1, -2, -3, and -4, each of which is constitutively expressed in the heart by fibroblasts, as well as myocytes. TIMP-1, -2, -3, and -4 are secreted proteins that act as the natural inhibitors of active forms of all MMPs, although the efficiency of MMP inhibition varies among the different members. The extant literature suggests that MMP activation can lead to progressive LV dilation, whereas TIMP expression favors progressive myocardial fibrosis.

Additional content on MMPs and TIMPs is available in an online supplement for this chapter ([Matrix Metalloproteinases](#)).

MicroRNAs. Recently, experimental studies from several laboratories have shown that microRNAs have a profound effect on cardiac remodeling. MicroRNAs are noncoding RNAs that pair with specific "target" mRNAs and negatively regulate their expression through translational repression or mRNA degradation (gene silencing). The binding specificity of microRNAs depends on complementary base pairing of approximately 6 nucleotide (nt) region at the 5' end of the microRNA with the 3' untranslated region (UTR) of the corresponding mRNA target. As shown in [Figure 22-14A](#), binding of microRNAs to their cognate target mRNAs commonly leads to decreased expression of target genes. Individual microRNAs modulate the expression of collections of messenger RNA targets that often have related functions, thereby governing complex biologic processes. Recent studies have suggested that microRNAs contribute to adverse/pathologic remodeling in experimental heart failure models.⁵⁰ As shown in [Figure 22-14B](#), microRNAs regulate key components of the remodeling process, including cardiac myocyte biology, cell fate, extracellular matrix remodeling, and neurohormonal activation. Given that microRNAs are coordinately upregulated in response to stress signals, and given that microRNAs regulate the expression levels of gene networks that determine the so-called heart failure phenotype, it is tempting to speculate that microRNAs, acting singly or in combination, may be responsible for modulating the transition from adaptive to pathologic cardiac remodeling. Moreover, it is possible that certain microRNAs may themselves become therapeutic targets using chemically modified oligonucleotides to target specific microRNAs and/or to disrupt the binding between a specific microRNA and a specific mRNA target.⁵⁰

Alterations in Left Ventricular Structure

The aforementioned changes in the biology of the failing myocyte, as well as in the failing myocardium, are largely responsible for the progressive LV dilation and LV dysfunction that occur during cardiac remodeling. As discussed further on, many of the structural changes that accompany LV remodeling may contribute to worsening heart failure ([Table e22-2](#)). Indeed, one of the first observations with respect to the abnormal geometry of remodeled ventricle was the consistent finding that the remodeled heart was not only larger but also more spherical in shape.²² An important point in this context is that a change in LV shape from a prolate ellipse to a more spherical shape results in an increase in meridional wall stress of the left

FIGURE e22-8 Disruption of the fibrillar ECM. **Left,** Scanning electron micrographs of normal human myocardial ECM in which the myocardium has been subjected to corrosion digestion to provide full relief of the collagen ECM. The scaffolding around where the myocytes are positioned is evident and underscores the complexity of the fibrillar collagen matrix. **Right,** Schematic representation depicting the collagen matrix and the potential effects of mechanical load and proteolytic digestion of fibrillar collagen support. The geometric alignment of myocytes is disrupted, with loss of the rigid architecture of the matrix. FIGURE 22-14 MicroRNAs (miRNAs) and the heart. **A**, The potential modes of miRNA-based regulation of gene expression are illustrated. Intronic microRNAs are encoded within an intron of a host gene. Messenger RNA splicing generates a protein coding transcript and a microRNA stem-loop. A common mechanism of miRNA function involves the modest repression of several mRNAs in a common biologic process by a single miRNA, most commonly through transcriptional silencing, or through enhanced mRNA degradation. Intronic miRNAs often regulate similar processes to that of the protein encoded by the host gene. AAA = polyadenylated tail of the transcript; pre-miRNA = precursor miRNA. **B**, Functional role of miRNAs in the normal and failing heart. A normal heart and a hypertrophic/failing heart are shown in schematic form, depicting miRNAs that contribute to normal function or pathologic remodeling. All arrows denote the normal action of each component or process. The miRNAs miR-1 and miR-133 are involved in the development of a normal heart (left) by regulating proliferation, differentiation and cardiac conduction. After cardiac injury (right), various miRNAs contribute to pathologic remodeling and the progression to heart failure: miR-29 blocks fibrosis by inhibiting the expression of ECM components, whereas miR-21 promotes fibrosis; miR-208 controls myosin isoform switching, cardiac hypertrophy, and fibrosis; and miR-23a promotes cardiac hypertrophy by inhibiting ubiquitin proteolysis, which itself inhibits hypertrophy. Hypoxia results in the repression of miR-320 and miR-199, which promote and block apoptosis, respectively. *Modified from Small EM, Olson EN: Pervasive roles of microRNAs in cardiovascular biology. Nature 469:336, 2011.*

ventricle, thereby creating a de novo energetic burden for the failing heart (Fig. e22-9). Inasmuch as the load on the ventricle at end-diastole contributes importantly to the afterload that the ventricle faces at the onset of systole, it follows that LV dilation itself will increase mechanical energy expenditure of the ventricle, which exacerbates the underlying problems with energy utilization in the failing ventricle (Fig. e22-10).

Cardiac Energetics. Energy transfer in the cardiac myocyte occurs in three stages, including uptake and metabolism, energy production through oxidative phosphorylation, and energy transfer by means of the creatine kinase shuttle (Fig. e22-11). Each stage of this process can lead to contractile dysfunction of the heart. Studies of myocardial ATP concentrations in humans with end-stage cardiomyopathy have shown that ATP concentration, the total adenine nucleotide pool (ATP, ADP, and AMP), creatine kinase (CK) activity (required for synthesis of ATP), the concentrations of creatine phosphate (CrP), and the CrP/ATP ratio are all decreased in heart failure. In addition, decreased levels of creatine phosphokinase have been reported, which would slow phosphocreatine shuttle, thereby further exacerbating energy utilization in the failing heart (the subject of a recent review⁵¹). Thus in the failing heart, key components of the cardiac energetic system are

downregulated. Unclear at present, however, is whether these energetic changes are biomarkers or drivers of LV dysfunction.

Although several mechanisms have been proposed to explain the fall in ATP content in heart failure, one mechanism that has received considerable attention relates to changes in substrate utilization in heart failure. Under normal conditions, the adult heart derives most of its energy through oxidation of fatty acids in mitochondria. The genes involved in this key energy metabolic pathway are transcriptionally regulated by members of the nuclear receptor superfamily, specifically the fatty acid-activated peroxisome proliferator-activated receptors (PPARs) and the nuclear receptor coactivator, PPAR-γ coactivator-1α (PGC-1α). In experimental heart failure models, an initial decrease is seen in the oxidation of fatty acids secondary to downregulation of fatty acid-metabolizing genes, with a resultant shift toward glycolytic metabolism (as recently reviewed⁵²). These observations have given rise to the suggestion that metabolic modulation may be beneficial in heart failure.

Additional content on this topic is presented in an online supplement for this chapter (Metabolic Modulation.)

In addition to loss of substrate, ATP generation may be impaired in the failing heart secondary to abnormalities in mitochondrial dynamics. Studies in yeast have demonstrated that maintaining normal mitochondrial morphology and function depends on the dynamic balance

FIGURE e22-9 Effect of changes in LV shape on LV wall stress. During LV remodeling, the ventricle undergoes a change in LV shape from a prolate ellipse (**A**) to a more spherical shape heart (**B**). As shown in **B**, the increase in short-axis dimension of the ventricle as the heart becomes more spherical in shape leads to an increase in meridional wall stress of the ventricle, thereby creating a de novo mechanical burden for the heart. σ_c = circumferential wall stress; σ_m = meridional wall stress. (From Mann DL: Left ventricular size and shape: Determinants of mechanical signal transduction pathways. *Heart Fail Rev* 10:95, 2005.)

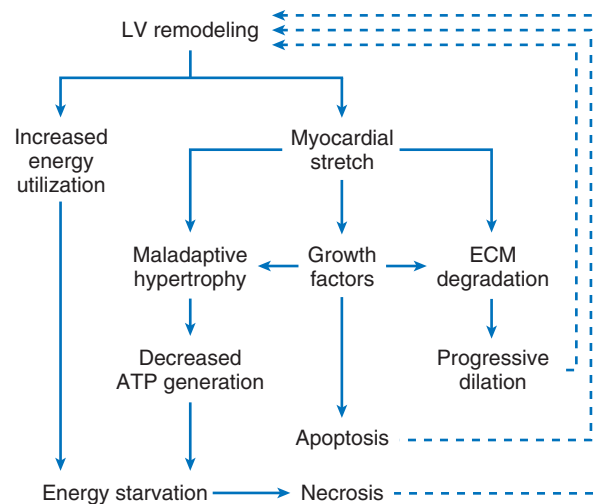

FIGURE e22-10 Self-amplifying nature of LV remodeling. LV remodeling results in increased afterload on the heart, which increases energy utilization and further stimulates cardiac growth through stretch-mediated activation of growth factors. The former contributes directly to a state of energy starvation, whereas the latter contributes to further cardiac remodeling including increased myocyte hypertrophy and further matrix remodeling. The sustained activation of growth stimuli also promotes apoptosis and myocardial fibrosis, which contribute to LV dysfunction and LV remodeling. (Modified from Katz AM: *Heart Failure*. Philadelphia, Lippincott Williams & Wilkins, 2000.)

FIGURE e22-11 Energy transfer in the cardiac myocyte occurs in three stages. Each stage may be the site of metabolic derangements causing or accompanying contractile dysfunction of the heart. The first stage is substrate uptake and metabolism (outlined in red). In this stage, substrates are broken down by β -oxidation and glycolysis to form acetyl-coenzyme A (acetyl-CoA), from which the Krebs cycle produces NADH and CO_2 . The second stage is energy production through oxidative phosphorylation (outlined in blue). Respiratory chain complexes in the mitochondria transfer electrons from NADH to oxygen. This creates a proton electrochemical gradient ($\Delta \mu H^+$) across the inner mitochondrial membrane, in addition to water and NAD. This gradient drives ATP synthase. Uncoupling proteins (UCPs) use this electrochemical gradient to create heat instead of ATP. The third stage is energy transfer via the creatine kinase shuttle (outlined in green). ATP is transferred to and consumed by myofibrillar ATPase and other reactions. ANT = adenine nucleotide translocase; CK_{mito} = mitochondrial creatine kinase isoenzyme; CK_{MM} = myofibrillar creatine kinase isoenzyme; Cr = free creatine; GLUT = glucose transporter; PCr = phosphocreatine; P_i = inorganic phosphate. (Modified from Neubauer S: *The failing heart—an engine out of fuel*. *N Engl J Med* 356:1140, 2007.)

of mitochondrial fusion and fission (division). Of note, abnormally small and fragmented mitochondria have been observed in end-stage dilated cardiomyopathy, myocardial hibernation, and congenital heart disease, suggesting that mitochondrial fusion/fission becomes dysregulated in cardiac disease. Although studies in heart failure are limited, the extant data suggest that there may be reduction in mitochondrial fusion, which would be predicted to lead to reduced oxygen consumption and/or alterations in mitochondrial metabolism. Moreover, abnormalities in mitochondrial dynamics may contribute to the cell death through apoptotic and/or autophagic cell signaling pathways.⁵³

In addition to the increase in LV end-diastolic volume, LV wall thinning also occurs as the ventricle begins to remodel. The increase in wall thinning along with the increase in afterload created by LV dilation leads to a functional “afterload mismatch” that may further contribute to a decrease in forward cardiac output. Increased LV wall stress also can lead to sustained expression of stretch-activated genes (angiotensin II, ET, and TNF) and/or stretch activation of hypertrophic signaling pathways. Moreover, the high end-diastolic wall stress might be expected to lead to episodic hypoperfusion of the subendocardium with resultant worsening of LV function, as well as increased oxidative stress, with the resultant activation of families of genes that are sensitive to free radical generation (e.g., TNF and IL-1 β). Another important mechanical problem that results from progressive LV dilation is that the papillary muscles are pulled apart, resulting in incompetence of the mitral valve and the development of “functional mitral regurgitation.” In addition to the loss of forward blood flow, mitral regurgitation results in further hemodynamic volume overloading of the ventricle. Taken together, the mechanical burdens engendered by LV remodeling might be expected to lead to increased LV dilation, decreased forward cardiac output, increased hemodynamic overloading (see Fig. e22-10), any or all of which are sufficient to contribute to worsening LV function independently of the neurohormonal status of the patient.

Reversibility of Left Ventricular Remodeling

Clinical studies have shown that medical and device therapies that reduce heart failure morbidity and mortality also lead to decreased LV volume and mass and restore a more normal elliptical shape to the ventricle. These salutary changes represent the summation of a series of integrated biologic changes in cardiac myocyte size and function (Table e22-3), as well as modifications in LV structure and organization that are accompanied by shifts of the LV end-diastolic pressure-volume relationship toward normal. For want of better terminology, these changes have been referred to collectively as “reverse remodeling.”

Moreover, in recognized subsets of patients, the heart is found to have undergone reverse remodeling either spontaneously or after medical or device therapies, and the subsequent clinical course is associated with freedom from future heart failure events.⁵⁴ This phenomenon has been referred to as “myocardial recovery.” Despite the frequent interchangeable use of the terms *myocardial recovery* and *reverse remodeling* to describe the reversal of various aspects of the heart failure phenotype with medical and device therapy, the literature suggests that there are important differences between these two phenomena and that myocardial recovery and reverse remodeling are not synonymous. The term *reverse remodeling*, as it is currently used, describes the biologic process of reversal of the cellular, myocardial, and anatomic abnormalities seen in the remodeled ventricle. As shown in Figure 22-15, patients whose hearts have undergone reverse remodeling may experience one of two potential outcomes: (1) freedom from future heart failure events and (2) recurrence of heart failure events. Based on the disparate clinical outcomes of reverse remodeling, it has been suggested that the term *myocardial recovery* should be used to describe the normalization of the molecular, cellular, myocardial, and LV geometric changes that are associated with freedom from future heart failure events, whereas the term *myocardial remission* should be used to refer to the normalization of the molecular, cellular, myocardial, and LV geometric changes that

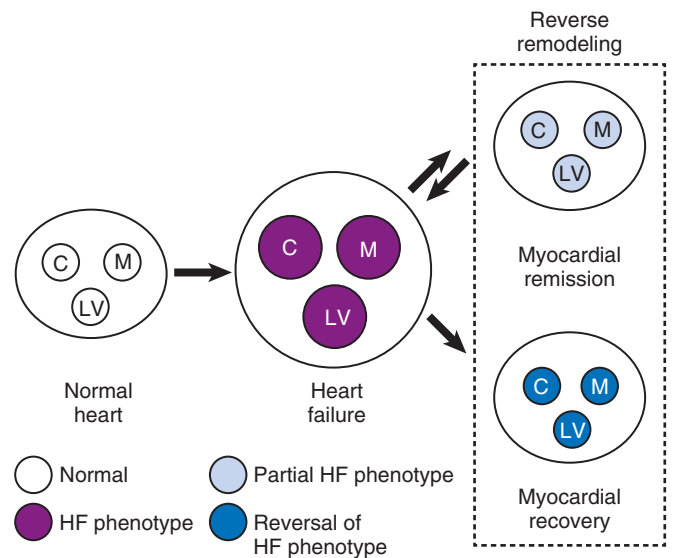

FIGURE 22-15 Reverse remodeling and myocardial recovery in heart failure (HF). Cardiac remodeling occurs secondary to abnormalities that arise in the biology of the cardiac myocyte (C), the myocardium (cardiocytes and extracellular matrix [M]), as well as LV geometry, which have collectively been referred to as the heart failure phenotype. During reverse remodeling there is a reversal of the abnormalities in the cardiac myocyte, as well as the extracellular matrix, leading to normalization of LV geometry. Reverse remodeling can lead to two clinical outcomes: (1) myocardial recovery, characterized by freedom from future cardiac events, or (2) myocardial remission, which is characterized by recurrence of heart failure events. (Modified from Mann DL, Barger PM, Burkhoff D: Myocardial recovery: Myth, magic or molecular target? *J Am Coll Cardiol* 60:2465, 2012.)

provoke cardiac remodeling that are insufficient to prevent the recurrence of heart failure in the face of normal and/or perturbed hemodynamic loading conditions (see Fig. 22-15).⁵⁴ Although the biologic differences between myocardial recovery and myocardial remission are not known, it is possible that myocardial remission represents reversal of the heart failure phenotype superimposed upon hearts that have sustained irreversible damage, whereas myocardial recovery represents reversal of the heart failure phenotype superimposed upon hearts that have not sustained irreversible damage.

FUTURE PERSPECTIVES

As described in this chapter, the clinical syndrome of heart failure can be considered in terms of several different clinical model systems, including a cardiorenal model, a hemodynamic model, and a neurohormonal model. Each of the models has strengths and weaknesses in terms of explaining the mechanisms responsible for heart failure, as well as developing effective new therapies for heart failure. Nonetheless, as noted previously, current models for explicating the mechanisms for heart failure are inadequate and do not adequately describe disease progression in heart failure. Moreover, they do not provide an adequate scaffold for understanding newer device therapies that appear to work through neurohormonally independent mechanisms. For this reason this chapter has emphasized the importance of cardiac remodeling as mechanism of disease progression in (biomechanical model¹). Future therapeutic advances are likely to require a more comprehensive understanding and analysis of the pathobiology of heart failure, particularly with regard to cell-cell interactions during LV remodeling, as well as the complex interactions that govern the process of reverse LV remodeling. In this regard, the emerging field of systems biology, which uses network theory to describe how the interrelationships between genes, proteins, and metabolites to determine functional changes at the level of the cell, tissue, and organ, may allow investigators to accelerate the pace of novel target identification, as well as potentially improve the likelihood of success in clinical trials.⁵⁵

**TABLE e22-3 Cellular and Molecular Determinants of Reverse Remodeling**

COMPONENT	ACE INHIBITOR	BETA BLOCKING AGENT	LVAD	CSD
Myocyte Defects				
Hypertrophy	Decreased	Decreased	Decreased	Decreased

TABLE e22-4 Classes of Matrix Metalloproteinases That Have Been Identified in Human Myocardium

CLASS	NUMBER	SUBSTRATE/FUNCTION	ABUNDANCE/ACTIVITY IN HEART FAILURE
<i>Collagenases</i> Interstitial collagenases	MMP-1	Collagens I, II, III, VII and basement membrane components	Decreased
Collagenase 3	MMP-13	Collagens I, II, III	Increased
Neutrophil collagenase	MMP-8	Collagens I, II, III and basement membrane components	
<i>Gelatinases</i> Gelatinase A	MMP-2	Gelatins, collagens, I, IV, V, VII and basement membrane components	Increased/Unchanged
Gelatinase B	MMP-9	Gelatins, collagens, IV, V, XIV and basement membrane components	Increased
<i>Stromelysins</i> Stromelysin 1	MMP-3	Fibronectin, laminin, collagens III, IV, IX and MMP activation	Increased
<i>Membrane-type MMPs</i> MT1-MMP	MMP-14	Collagens I, II, III, fibronectin, laminin-1, activates pro-MMP-2 and pro-MMP-13	Increased

Matrix Metalloproteinases

The MMPs represent a family of zinc-dependent proteases that play a role in an important role in normal tissue remodeling, as well as in pathologic processes such as inflammation, tumor invasion, and metastasis. The MMPs are secreted as inactive zymogens that must be activated by cleavage of the N-terminal sequence of the propeptide domain, which allows the Zn²⁺-binding site of the catalytic domain to become exposed. The exception is membrane-type MMP 1 (MT-MMP1), which is cell surface-bound and is processed before cell surface localization by a furin-dependent mechanism.

The MMPs can be classified into subgroups based on substrate specificity or structure, or both (Table e22-4). This classification includes the collagenases (e.g., MMP-1 and MMP-13), the stromelysins (e.g., MMP-3), the gelatinases (e.g., MMP-9 and MMP-2), and the membrane-type MMPs (MT-MMPs).

Once activated, the MMPs are capable of degrading all of the ECM components. Myocardial MMP abundance and activation have been assessed in end-stage human heart failure.¹ Although most MMP species are increased in heart failure, the abundance of MMP-1 is significantly reduced.² Furthermore, different levels of MMP-2 abundance and activity have been observed in congestive heart failure myocardium of ischemic or nonischemic origin. Loss of

TIMP-mediated inhibitory control has been suggested as a reason for enhanced MMP activity in patients with dilated cardiomyopathy, in whom a reduction in relative myocardial levels of TIMP-1 and TIMP-3 and/or alterations in MMP/TIMP binding have been reported. This disparity between MMP and TIMP levels favors a persistent MMP activation, enhanced ECM proteolysis, and progressive LV dilation.² The role of MMP inhibition in the postinfarction setting was examined in humans in the PREMIER (Prevention of Myocardial Infarction Early Remodeling) trial, in which 253 patients with ST-segment elevation myocardial infarction and an ejection fraction between 15% and 40% were randomly assigned in a 1:1 ratio to receive placebo or an MMP inhibitor (PG-116800) with high affinity for MMP-1, -3, -8, -9, -13, and -14. In this small study, MMP inhibition failed to reduce LV remodeling or improve clinical outcomes after myocardial infarction. The failure to show a benefit may have been related to inadequate dosing of the MMP inhibitor.³

Metabolic Modulation

Optimization of myocardial energy utilization represents another unique approach to the treatment of heart failure. As discussed further on, a number of derangements in myocardial metabolism may partly explain the decrease in high-energy phosphates and phosphocreatine that have been reported in the failing heart. In the normal heart, free fatty acids are the preferred fuel for cardiac myocytes, producing roughly four times the ATP per mole of substrate used when compared with glucose. However, fatty acid oxidation is less efficient than glucose oxidation, requiring 10% to 12% more oxygen consumption to produce equivalent amounts of ATP. Under conditions in which oxygen is the limiting substrate, such as in the failing heart, glycolysis becomes the more efficient pathway, requiring less oxygen compared with oxidation of free fatty acid. Fatty acid oxidation is physiologically regulated at several levels, including the concentration of circulating free fatty acid substrate, at the level of entry into the mitochondrion, and by the activity of several of the mitochondrial matrix enzymes that constitute the beta-oxidation pathway.¹ On the other hand, the rate of glucose oxidation is regulated primarily, although not exclusively, by the rate of fatty acid oxidation, which inhibits the pyruvate dehydrogenase complex (PDH), the activity of which is rate-limiting for glucose oxidation (see Fig. e22-12). Inhibition of pyruvate dehydrogenase can lead to increased glucose utilization through conversion of pyruvate to lactate, resulting in progressive tissue acidosis and impaired myocyte contractility (Fig. 22e-12A). From a theoretical perspective, shifting energy utilization from free fatty acids to glucose would optimize metabolic efficiency, reverse abnormalities in the cellular milieu, and improve cardiac function (Fig. 22e-12B). Although the results of the studies on substrate utilization in heart failure often have yielded conflicting results, the aggregate data support the concept that rates of fatty acid oxidation are normal or slightly increased in pathologic hypertrophy-related early heart failure, whereas fatty acid oxidation is decreased during the later stages of heart failure, accompanied by an absolute or relative increase in glucose utilization during late stages of heart failure.²

The prototype partial inhibitors of fatty acid oxidation (pFOX), etomoxir, oxfenicine, and perhexiline, act by inhibiting carnitine palmitoyltransferase I (CPT I), the gatekeeper of fatty acid entry to the mitochondrion (see Fig. e22-12A). These agents shift energy utilization from free fatty acids to glucose by decreasing oxidation of free fatty acids. However, in the absence of any apparent feedback from CPT I activity to sarcolemmal fatty acid import, CPT I inhibitors can cause accumulation of unmetabolized lipids in cardiac myocytes, which may lead to lipotoxicity-induced cardiac myocyte cell death. Etomoxir is an oxirane carboxylic acid derivative that indirectly promotes increased glucose oxidation through inhibition of CPT I. In an open-label, uncontrolled trial conducted in 10 patients with NYHA class II to III heart failure, treatment with etomoxir for 3 months was associated with a significant improvement in LV ejection fraction (LVEF), cardiac output at peak exercise, and clinical status.³ Subsequent phase II studies with etomoxir were halted because the compound did not have the expected efficacy in the treatment of heart failure (data from MediGene 2002 Annual Report [accessed March 26, 2003]). Although oxfenicine was shown to be beneficial in the canine rapid pacing model of heart failure, in other animal models treatment with oxfenicine resulted in a dose-related increase in cardiac mass, as well as an increase in liver and kidney weights. Perhexiline currently is in clinical use as an antianginal agent. Regarding the early reports of hepatotoxicity with this agent, the hepatotoxicity occurred in patients with a genetic variant of a cytochrome P-450 enzyme (slow hydroxylation), which resulted in drug accumulation, as well as accumulation of phospholipids in the liver and nerves. The risk of toxic effects is virtually eliminated by maintaining plasma concentrations between 150 and 600 ng/mL, at which levels the drug still remains effective.³ Perhexiline showed promise

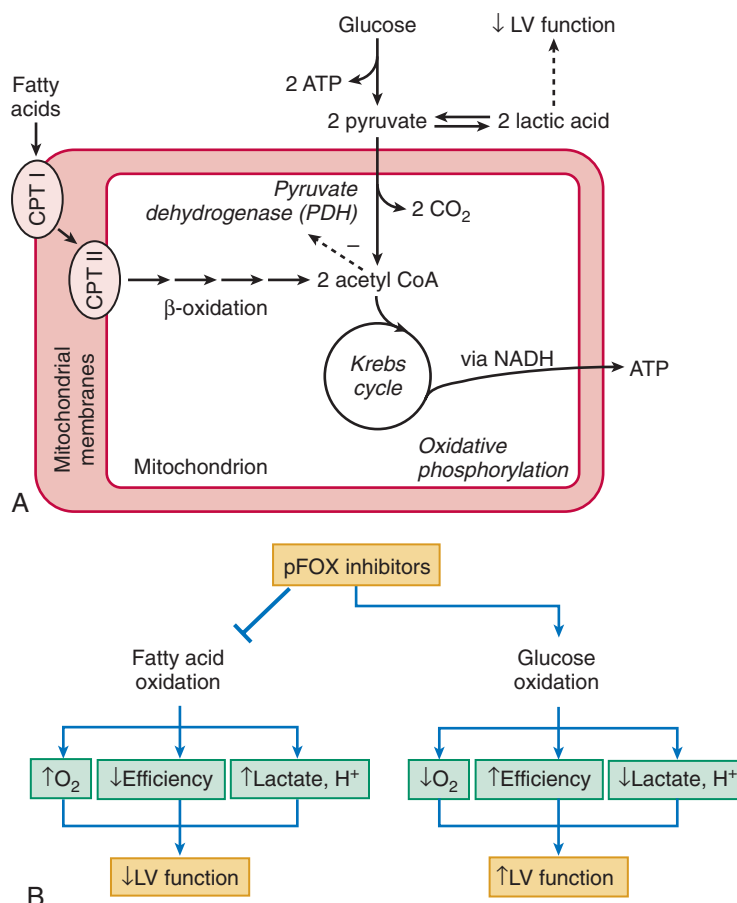

FIGURE e22-12 Metabolism of free fatty acids and glucose. **A**, Metabolic pathway for glucose metabolism and fatty acid oxidation. **B**, Effects of switching metabolism from fatty acid beta-oxidation to glucose oxidation (under conditions in which oxygen supply is rate-limiting) using partial inhibitors of fatty acid oxidation (pFOX). (From Dimmeler S, Mann DL, Zeiher AM: *Emerging therapies and strategies in the treatment of heart failure*. In Bonow RO, Mann DL, Zipes DP, Libby P [eds]: *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 9th ed. Philadelphia, Saunders, 2012, pp 627-643.)

for use in adjunctive therapy for heart failure in a small short-term randomized double-blind clinical trial in patients with ischemic and nonischemic cardiomyopathy. In this study, 8 weeks of treatment with perhexiline showed benefit in the combined primary endpoint of increased peak oxygen uptake and LVEF and improvement in quality of life (as measured using the Minnesota Living with Heart Failure Questionnaire). Of importance, maximum oxygen uptake was increased significantly in both the ischemic and nonischemic groups, suggesting that the benefit of perhexiline was not entirely anti-ischemic.⁴ Although there remains some optimism that CPT I inhibitors can be used for adjunctive therapy in heart failure, other pFOX inhibitors may have fewer side effects.

The pFOX inhibitors trimetazidine and ranolazine also were originally developed as antianginal agents. Trimetazidine is a piperazine compound that has been widely used outside of the United States as antianginal agent. Trimetazidine has no discernible vasodilator properties at rest or during dynamic exercise and has a very favorable side effect profile. The exact mechanism of action of trimetazidine is not known, but it appears to work, at least in part, through inhibition of long-chain 3-ketoacyl coenzyme A thiolase, a crucial enzyme in the terminal steps of mitochondrial beta-oxidation. As discussed next, several small clinical trials have shown improvements in ejection performance, reverse cardiac remodeling, and improvement in NYHA functional class with trimetazidine.³

Trimetazidine

Trimetazidine has been evaluated in a number of small clinical trials in patients with both ischemic and nonischemic cardiomyopathy.^{1,3}

Two months of treatment with trimetazidine resulted in significant improvement in LVEF at rest and enhanced LV wall motion during a dobutamine stress test compared with placebo in patients with NYHA class II and III heart failure.¹ In two recent small clinical studies, trimetazidine was shown to improve systolic LV function in patients with diabetes and ischemic cardiomyopathy when compared with placebo.^{1,5} By contrast, another study, which assessed the effects of trimetazidine in patients with heart failure who were diabetic, demonstrated no significant effect on exercise capacity and only minor effects on LV systolic function.³ In a study that specifically enrolled elderly patients with coronary artery disease and LVEF less than 50%, the patients in the group that received 6 months of trimetazidine on top of standard therapy showed a significantly greater improvement in LVEF (approximately 7%), as well as smaller LV end-diastolic and systolic dimensions. In addition, the trimetazidine treatment group had improved NYHA functional class and quality of life scores (on the Minnesota Living with Heart Failure Questionnaire). These findings have been confirmed in recent larger trials with longer-term follow-up (for 18 to 24 months), which also have shown improvements in LVEF, reduction in LV volumes, and improvement in NYHA functional class in patients with ischemic cardiomyopathy (LVEF <50%).³ In view of the antianginal effects of trimetazidine, it is perhaps not surprising that this agent led to improvements in LV function and NYHA functional class in patients with ischemic cardiomyopathy. However, a recent study with trimetazidine also included patients with nonischemic cardiomyopathy and showed similar increases in LVEF and reductions in LV end-systolic volume and similar trends for improved quality of life and exercise capacity in both the ischemic and nonischemic groups.⁶ Thus it appears that trimetazidine has both functional and physiologic benefits regardless of the heart failure etiology.

Ranolazine

Ranolazine (Ranexa) is a novel anti-ischemic drug that has been FDA-approved for the treatment of angina. The principal mechanism of action for this drug as an antianginal remains controversial, although recent studies suggest that the antianginal effects of ranolazine may be related to decreased sodium entry into cells by inhibiting the late sodium current. Although no clinical trials have yet been reported using ranolazine in patients with dilated cardiomyopathy, a recent proof-of-concept study in patients with heart failure with preserved ejection fraction showed reduced left ventricular filling pressures after intravenous application.⁷ Another study is still ongoing (NCT01505179) (see Chapter 27).

Glucagon-like Peptide-1

Sustained activation of the sympathetic nervous system in heart failure leads to increased lipolysis, with a subsequent rise in levels of circulating fatty acids with a resultant insulin resistance. Although the exact role of insulin resistance in heart failure is not known, studies with the incretin hormone glucagon-like peptide-1 (GLP-1), which increases postprandial insulin secretion and improves insulin sensitivity, have demonstrated improvements in contractility in both experimental and human heart failure. In a study of 12 patients with NYHA class III or IV heart failure, a continuous infusion of GLP-1 for 12 weeks improved LVEF (21% to 27%) and functional capacity, even in the nondiabetic patients.⁸ Similarly, in a study that included 10 patients with acute myocardial infarction and LV systolic dysfunction (LVEF <40%), a 72-hour continuous infusion of GLP-1 was associated with a significant improvement in LVEF, as well as global and regional wall motion.⁹ In contrast with these early encouraging findings, no improvement was observed in cardiac index, LV ejection fraction, or brain natriuretic peptides levels in a small study comprising 20

nondiabetic patients with NYHA class II or III heart failure after a 48-hour infusion of GLP-1. Moreover, a small but potentially concerning rise in heart rate and diastolic blood pressure was reported in this study.¹⁰ Exenatide, a GLP-1 agonist, increased both heart and cardiac index in men with type 2 diabetes and NYHA class III or IV heart failure ($N = 20$), along with a decrease in pulmonary capillary wedge pressure, in a 2-day crossover design study that involved intravenous infusions during two consecutive days with either (1) exenatide (0.12 pmol/kg/min) or (2) placebo for 6 hours, followed by a washout period for 18 hours. No adverse effects were observed in this short-term study.¹¹

At present, GLP-1 has to be given as an infusion, and it has a very short half-life, which may limit its clinical applicability. Alternative GLP-1 agonists with longer half-lives, or agents that inhibit the catabolism of GLP-1 by dipeptidyl peptidase IV (DPP-IV), may need to be developed for this approach to be useful clinically in patients with heart failure.

Micronutrient Supplementation

The heart requires a continuous supply of energy-providing substrates and amino acids in order to maintain normal structure and function. In heart failure, alterations in substrate metabolism, the tricarboxylic acid cycle, or oxidative phosphorylation may contribute to contractile dysfunction. For example, deficiencies in coenzyme Q10 (CoQ10), L-carnitine, amino acids, and thiamine and other B vitamins have been documented in the failing heart,¹² raising the interesting possibility that micronutrient supplementation could improve the abnormal energetic milieu of the failing heart. Although a number of supplementation trials of key micronutrients involved in cardiac metabolism, such as including CoQ10, L-carnitine, thiamine, and taurine, have yielded promising results in patients with heart failure, none of these clinical trials have provided conclusive results (as summarized in a published review¹²). Because of the absence of definitive clinical trial data in this area, the American College of Cardiology/American Heart Association practice guidelines do not recommend the use of nutritional supplements as a treatment for heart failure in patients with current or previous heart failure symptoms.¹³

HEART FAILURE DEFINITIONS

Heart failure (HF) is a complex clinical syndrome resulting from structural and functional impairment of ventricular filling or ejection of blood. Although the clinical syndrome of HF may arise as a consequence of abnormalities or disorders involving all aspects of cardiac structure and function, most patients have impairment of myocardial performance, with findings ranging from normal ventricular size and function to marked dilation and reduced function. Although symptoms of HF frequently depend on the presence of elevated left- or right-sided heart filling pressures, the designation “congestive” in this context is no longer preferred, because many patients do not have overt congestion at the time of evaluation.

Approximately half of the patients with HF have normal left ventricular function, that is, HF with preserved ejection fraction (HFpEF) (see Chapter 27); the balance have HF with reduced ejection fraction (HFrEF) (see Chapter 25).¹ HFpEF generally is defined as a left ventricular ejection fraction of 50% or greater, whereas HFrEF is defined as an ejection fraction below 40%. Because treatment strategies for treating HF are based on these two categories, these distinctions are crucial.

Two useful methods to classify patients with HF are recognized. The American College of Cardiology/American Heart Association (ACC/AHA) HF staging approach (see Fig. 25-6) emphasizes the importance of development and progression of disease,² (see Chapter 25G) whereas the New York Heart Association (NYHA) functional classification focuses more on exercise tolerance in persons with established HF (Table 23-1). Although suffering from considerable subjectivity, the NYHA functional classification is widely used. Use of both systems in conjunction provides a reasonable framework for clinician communication and patient prognostication.

When HF is suspected, the goals of the clinical assessment are to determine whether HF is present, define the underlying cause, assess severity of the disease and the patient's prognosis, and identify comorbid conditions that can influence the clinical course and response to treatment. When the diagnosis of HF has already been established, the goals are similar, with a particular focus on optimal therapeutic intervention.

Although the diagnosis of HF can be straightforward when the patient presents with a constellation of the classic signs and symptoms in the appropriate clinical setting (Tables 23-2 and 23-3), no sign or symptom alone can define the presence or severity of HF. Furthermore, the detection of diagnostic physical findings in HF is an imprecise science, often requiring other diagnostic tools. Thus, as depicted in Figure 23-1, the clinical assessment of HF most often

depends on information that is gleaned from a variety of sources including the history (both past and present), physical examination, laboratory tests, cardiac imaging, and functional studies.

THE MEDICAL HISTORY AND
PHYSICAL EXAMINATION

A complete medical history and carefully focused physical examination are the foundation of the assessment of patients with HF, providing important information regarding etiology of HF, identifying possible exacerbating factors, and lending pivotal data for proper management (Chapter 11). The information obtained guides the further direction of the patient's evaluation and enables the clinician to make the most judicious use of additional tests. Furthermore, the history helps to evaluate incongruent results that may emerge during the diagnostic process, and it can avoid needless further testing.

Heart Failure Symptoms

Patients with HF may complain of a vast array of symptoms, the most common of which are listed in Table 23-1. Although none of these are entirely sensitive or specific for identifying the presence of severe congestion (Table 23-4), some are more reliable than others for this indication. None are specific to HFpEF versus HFrEF.

Worsening dyspnea is a cardinal symptom of HF and typically is related to increases in cardiac filling pressures but also may represent restricted cardiac output.³ The absence of worsening dyspnea, however, does not necessarily exclude the diagnosis of HF, because patients may accommodate symptoms by substantially modifying their lifestyle. Probing more deeply into the current level of activity may uncover a decline in exercise capacity that is not immediately apparent. Dyspnea at rest often is mentioned by patients hospitalized with HF and has a high diagnostic sensitivity and significant prognostic ramifications in this population. However, it also is cited by patients with many other medical conditions, so that the specificity and positive predictive value for dyspnea at rest alone are low. Patients may sleep with the head elevated to relieve dyspnea while recumbent (orthopnea); additionally, dyspnea may occur specifically in recumbency on the left side (trepopnea). Paroxysmal nocturnal dyspnea, shortness of breath developing in recumbency, is one of the most highly reliable indicators of HF. Nocturnal cough is a frequently overlooked symptom of HF. These symptoms all typically reflect pulmonary congestion, whereas a history of weight gain, increasing abdominal girth, early satiety, and the onset of edema in dependent

TABLE 23-1 American College of Cardiology/American Heart Association (ACC/AHA) Stages of Heart Failure (HF) Compared with the New York Heart Association (NYHA) Functional Classification

ACC/AHA STAGES			NYHA FUNCTIONAL CLASSIFICATION	
A	At high risk for HF but without structural heart disease or HF symptoms	None		
B	Structural heart disease but without signs or symptoms of HF	I	No limitation of physical activity Ordinary physical activity does not cause symptoms of HF	
C	Structural heart disease with previous or current symptoms of HF	I	No limitation of physical activity Ordinary physical activity does not cause symptoms of HF	
		II	Slight limitation of physical activity Comfortable at rest, but ordinary physical activity results in symptoms of HF	
		III	Marked limitation of physical activity Comfortable at rest, but less than ordinary activity causes symptoms of HF	
D	Refractory HF requiring specialized interventions	IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest	

TABLE 23-2 Using the Medical History to Assess the Patient with Heart Failure (HF)

Symptoms and Signs Associated with HF
Fatigue
Shortness of breath at rest or during exercise
Dyspnea
Tachypnea
Cough
Diminished exercise capacity
Orthopnea
Paroxysmal nocturnal dyspnea
Nocturia
Weight gain/weight loss
Edema (of the extremities or scrotum or elsewhere)
Increasing abdominal girth or bloating
Abdominal pain (particularly if confined to the right upper quadrant)
Loss of appetite or early satiety
Cheyne-Stokes respirations (often reported by a family member rather than the patient)
Somnolence or diminished mental acuity
Historical Information Helpful in Determining if Symptoms Are Due to HF
A past history of HF
Cardiac disease (e.g., coronary artery, valvular or congenital disease, previous myocardial infarction)
Risk factors for HF (e.g., diabetes, hypertension, obesity)
Systemic illnesses that can involve the heart (e.g., amyloidosis, sarcoidosis, inherited neuromuscular diseases)
Recent viral illness or history of HIV infection or Chagas disease
Family history of HF or sudden cardiac death
Environmental and/or medical exposure to cardiotoxic substances
Substance abuse
Noncardiac illnesses that could affect the heart indirectly (including high-output states such as anemia, hyperthyroidism, and arteriovenous fistulas)

organs (extremities or scrotum) indicate right heart congestion; non-specific, right upper quadrant pain due to congestion of the liver is common in those with significant right-sided HF and may be incorrectly attributed to other conditions. Another cardinal symptom of HF is fatigue, generally held to be reflective of reduction in cardiac output as well as abnormal skeletal muscle metabolic responses to exercise.⁴ Other causes of fatigue in HF may include major depression, anemia, renal dysfunction, and endocrinologic abnormalities, as well as side effects of medications. Cachexia may be prominent and lead to an extensive workup for malignancy.

Other Historical Information

Information about a patient's past and current medical problems and a multigenerational family history as well as social history provides

TABLE 23-3 Physical Findings in Heart Failure

Tachycardia
Extra beats or irregular rhythm
Narrow pulse pressure or thready pulse*
Pulsus alternans*
Tachypnea
Cool and/or mottled extremities*
Elevated jugular venous pressure
Dullness and diminished breath sounds at one or both lung bases
Rales, rhonchi, and/or wheezes
Apical impulse displaced leftward and/or inferiorly
Sustained apical impulse
Parasternal lift
S3 and/or S4 heart sounds (either palpable and/or audible)
Tricuspid or mitral regurgitant murmur
Hepatomegaly (often accompanied by right upper quadrant discomfort)
Ascites
Presacral edema
Anasarca*
Pedal edema
Chronic venous stasis changes

*Indicative of more severe disease.

the background upon which symptoms are interpreted and a management plan is designed. The presence of hypertension, coronary artery disease and/or diabetes is particularly helpful since these conditions account for approximately 90% of the population attributable risk for HF in the United States.⁵ The medical history should also focus on what drugs are taken by the patient; notable agents associated with incident HF include cancer chemotherapy,⁶ diabetes drugs (e.g., thiazolidinediones), ergot-based antimigraine drugs, appetite suppressants, certain antidepressants and antipsychotic agents (notably including clozapine), decongestants such as pseudoephedrine (owing to its ability to trigger severe hypertension), and anti-inflammatory agents such as the antimalarial drug hydroxychloroquine (uncommonly associated with an infiltrative cardiomyopathy) and nonsteroidal anti-inflammatory drugs (NSAIDs). The NSAIDs are well recognized to lead to HF through their ability to worsen renal function, trigger hypertension, and lead to fluid retention, particularly in elderly persons.⁷ A history of use of herbal remedies and dietary supplements should be obtained. Environmental or toxic exposures including alcohol or drug abuse should be carefully sought. A multigenerational family history should be taken for previous HF or sudden cardiac death. Information about the presence of comorbid conditions (as described later in the chapter) is essential in devising management plans. Although most disorders causing HF are cardiac, it is worth remembering that some systemic illnesses (e.g., anemia, hyperthyroidism) can cause this syndrome without direct cardiac involvement (see [Chapter 25](#)).

TABLE 23-4 Sensitivity and Specificity of History and Physical Findings for Diagnosis of Elevated Filling Pressures in Patients with Heart Failure (HF)*

FINDING	FREQUENCY	SENSITIVITY	SPECIFICITY	PREDICTIVE VALUE		LR		OR (95% CI)
				Positive	Negative	Positive	Negative	
Rales (heard over $\geq 1/3$ lung fields)	26/192	15	89	69	38	1.32	1.04	1.4 (0.6, 3.4)
S3	123/192	62	32	61	33	0.92	0.85	0.8 (0.4, 1.5)
Ascites (moderate/massive)	31/192	21	92	81	40	2.44	1.15	2.8 (1.1, 7.3)
Edema ($\geq 2+$)	73/192	41	66	67	40	1.20	1.11	1.3 (0.7, 2.5)
Orthopnea (requiring ≥ 2 pillows)	157/192	86	25	66	51	1.15	1.80	2.1 (1, 4.4)
Hepatomegaly (liver edge palpable at >4 fingerbreadths beyond costal margin)	23/191	15	93	78	39	2.13	1.09	2.3 (0.8, 6.6)
Hepatojugular reflux	147/186	83	27	65	49	1.13	1.54	1.7 (0.9, 3.5)
JVP ≥ 12 mm Hg	101/186	65	64	75	52	1.79	1.82	3.3 (1.8, 6.1)
JVP <8 mm Hg	18/186	4.3	81	28	33	0.23	0.85	0.2

JVP = jugular venous pressure; LR = likelihood ratio; OR = odds ratio.

*Values expressed as percent unless otherwise indicated.

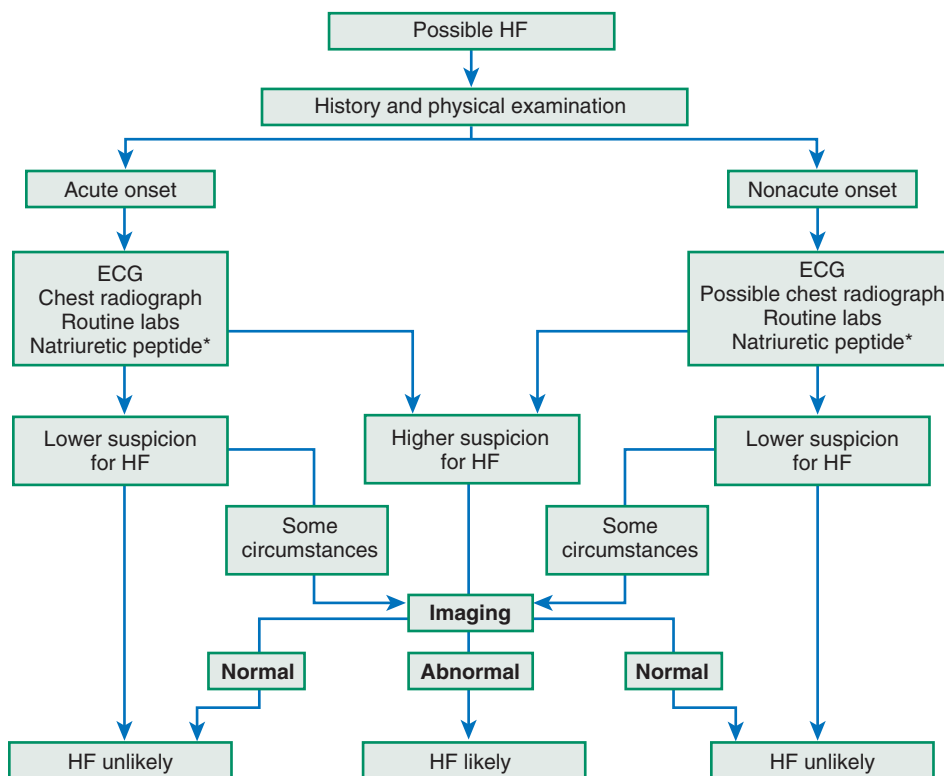

FIGURE 23-1 Flow chart for the evaluation of patients with HF. Appropriate criteria for natriuretic peptide testing (*) to identify or exclude HF are summarized in Table 23-6. The diagnosis of HF is made using a combination of clinical judgment and initial and subsequent testing. After a thorough history and physical examination, along with initial diagnostic testing, imaging (such as with echocardiography) may still be necessary in ambiguous cases to definitively identify or exclude HF. Cut-off values for BNP and NT-proBNP are displayed in Table 23-6. ECG = electrocardiogram.

The Physical Examination

The physical findings listed in Table 23-2 complement information from the medical history in defining the presence and severity of HF (see also Chapter 11). The signs of HF have been extensively described, and much as with the history of patients with HF, components of the physical examination have variable sensitivity and specificity for the diagnosis (see Table 23-4),⁸ owing in part to the subtlety of some physical findings as well as variability in the physical diagnostic skills of the examiner. No physical finding in HF is absolutely pathognomonic for HFpEF versus HFrEF.⁹

An evaluation for the presence and severity of HF should include consideration of the patient's general appearance, measurement of vital signs in the seated and standing positions, examination of the heart and pulses, and assessment of other organs for evidence of congestion or hypoperfusion or indications of comorbid conditions.

The patient's general appearance conveys vital information. The examiner should assess the patient's body habitus and state of alertness, as well as whether the patient is comfortable, short of breath, coughing, or in pain. The skin examination may show pallor or cyanosis secondary to underperfusion, stigmata of alcohol abuse (such as spider angiomas or palmar erythema), erythema nodosum due to sarcoidosis, bronzing due to hemochromatosis, or easy bruising from amyloidosis; additional findings supporting amyloidosis include deltoid muscle infiltration (leading to the "shoulder pad sign"), tongue hypertrophy, and bilateral thenar wasting from carpal tunnel syndrome.

Cheyne-Stokes respiration (also referred to as periodic or cyclic respiration) is common in advanced HF and usually is associated with low cardiac output and sleep-disordered breathing (see also Chapters 25 and 75). The presence of Cheyne-Stokes respiration generally is indicative of an adverse prognosis.¹⁰

The details of inspection and palpation of the heart are discussed in Chapter 11. By observing or palpating the apical impulse, the examiner can rapidly determine heart size and quality of the point of maximal impulse. In cases of severe HF, a palpable third heart sound may be present.

Cardiac auscultation (Chapter 11) is a crucial part of HF evaluation.

A characteristic holosystolic murmur of mitral insufficiency is heard in many patients with HF. Tricuspid insufficiency, which also is common,

can be differentiated from mitral insufficiency by the location of the murmur at the left sternal border, an increased intensity of the murmur during inspiration and the presence of prominent “V” waves in the jugular venous waveform. Both mitral and tricuspid insufficiency murmurs may become softer as volume overload is treated, and a reduction in ventricular size improves valve competency. Aortic stenosis is an important cause of HF, because its presence greatly alters management. The presentation of aortic stenosis may be subtle, however, because the intensity of the murmur depends on blood flow across the valve, and this may be reduced as HF develops.

The presence of a third heart sound is a crucially important finding and suggests increased ventricular filling volume; although difficult to identify, a third heart sound is highly specific for HF and carries a substantial prognostic meaning. A fourth heart sound usually indicates ventricular stiffening. In advanced HF, the third and fourth heart sounds may be superimposed, resulting in a summation gallop.

A key objective of the examination in patients with HF is to detect and quantify the presence of volume retention, with or without pulmonary and/or systemic congestion.¹¹ As with symptoms, evidence of congestion does not always indicate with certainty that HF is present, nor does absence of manifest congestion definitively exclude the diagnosis. Patients with HFpEF and those with HFrEF do not generally show significant differences in frequency or significance of the stigmata of volume overload.¹²

The most definitive method for assessing a patient's volume status by physical examination is by the measurement of jugular venous pressure (JVP), which is discussed in detail in [Chapter 11](#). An elevated JVP has good sensitivity (70%) and specificity (79%) for elevated left-sided filling pressure.⁸ The sensitivity and specificity of the JVP in detecting congestion can be considerably improved by exerting pressure on the right upper quadrant of the abdomen while assessing venous pulsations in the neck (hepatojugular reflux). Changes in JVP with therapy usually parallel changes in left-sided filling pressure. Limitations of JVP assessment include difficulties in its evaluation due to body habitus as well as significant interobserver variability in its estimation. Increase in the JVP may lag behind left-sided heart filling pressures or may not rise at all if pulmonary artery pressure is increased to the extent that right ventricular failure or tricuspid insufficiency occur. Conversely, the JVP may be elevated without an increase in left ventricular filling pressures in patients with pulmonary arterial hypertension, in those with isolated right ventricular pressure, or when isolated severe tricuspid regurgitation is present.

Although pulmonary congestion is exceedingly common in HF, physical findings indicating its presence are variable, and many are nonspecific. Dullness to percussion and diminished breath sounds at one or both lung bases suggests the presence of a pleural effusion. Bilateral pleural effusions are most common but when an effusion is present unilaterally, it is usually right sided with only approximately 10% occurring exclusively on the left side.

Leakage of fluid from pulmonary capillaries into the alveoli can be manifested as rales or rhonchi, and wheezing may occur with reactive bronchoconstriction. Pulmonary rales due to HF usually are fine in nature and extend from the base upwards, whereas those due to other causes (e.g., pulmonary fibrosis) tend to be coarser. Of note, rales or rhonchi may be absent in congested patients with advanced HF; this may reflect compensatory increase in local lymphatic drainage. So-called cardiac asthma is due to the physical presence of fluid in the bronchial wall, as well as secondary bronchospasm,¹³ and can commonly result in an incorrect diagnosis of obstructive airways disease exacerbation, with consequent mistriage and incorrect therapy with bronchodilators; such incorrect management may be associated with increased risk of death.¹⁴

Lower-extremity edema is a common finding in volume-overloaded patients with HF but may commonly be the result of venous insufficiency (particularly after saphenous veins have been harvested for coronary artery bypass grafts) or as a side effect of medications (e.g., calcium channel blockers). Careful inspection of the JVP will help improve the specificity of pedal edema for HF.

Detection of reduced cardiac output and systemic hypoperfusion is a key component of the examination. Although patients with poor

		Congestion at rest? (e.g., orthopnea, elevated jugular venous pressure, pulmonary rales, S3 gallop edema)	
		No	Yes
Low perfusion at rest? (e.g., narrow pulse pressure, cool extremities, hypotension)	No	Warm and dry	Warm and wet
	Yes	Cool and dry	Cool and wet

FIGURE 23-2 Schema for categorizing patients with HF on the basis of perfusion (warm versus cold) and presence of congestion (dry versus wet). The four categories of HF identified in this schema have different treatment strategies. (Based on data from Nohria A, Tsang SW, Fang JC, et al: Clinical assessment identifies hemodynamic profiles that predict outcomes in patients admitted with heart failure. *J Am Coll Cardiol* 41:1797, 2003.)

systemic perfusion usually have low systolic and narrow pulse pressures as well as weak and thready pulses, this relationship is not exact. Many patients with systolic blood pressures in the range of 80 mm Hg (or even lower) may have adequate perfusion, whereas others with reduced cardiac output may maintain blood pressure in the normal range at the expense of tissue perfusion by greatly increasing systemic vascular resistance. Findings suggesting reduced cardiac output include poor mentation, reduced urine output, mottled skin, and cool extremities. Of these, cool extremities are the most broadly useful.

Assessment for systemic congestion, taken together with evaluation for reduced cardiac output, may be useful to separate patients with HF ([Fig. 23-2](#)) into “dry/warm” (uncongested with normal perfusion), “wet/warm” (congested with normal perfusion, the most common combination found in decompensated HF), “dry/cold” (uncongested but hypoperfused), and “wet/cold” (cardiogenic shock) categories,¹⁵ as discussed in [Chapter 24](#).

ROUTINE ASSESSMENT

A suggested algorithm for the diagnostic evaluation of HF is presented in [Figure 23-1](#). The laboratory testing and imaging modalities described next provide important information for the diagnosis and management of patients with suspected or proven HF.

Chest Radiography

Despite advances in other imaging technologies, plain chest radiography ([see also Chapter 15](#)) remains a very useful component of the assessment, particularly when the clinical presentation is ambiguous. Results of chest radiography are additive to clinical variables from history and physical examination, and similarly complement the results of biomarker testing. Accordingly, chest radiography should be a routine part of the early evaluation of patients presenting with symptoms suggestive of acutely decompensated HF.

The classic chest radiograph appearance in patients with pulmonary edema is a “butterfly” pattern of interstitial and alveolar opacities bilaterally fanning out to the periphery of the lungs. Many patients, however, present with more subtle findings, of which increased interstitial markings including Kerley B lines (thin horizontal linear opacities extending to the pleural surface caused by accumulation of fluid in the interstitial space), peribronchial cuffing, and evidence of prominent upper lobe vasculature (indicating pulmonary venous hypertension) are the most prominent. Pleural effusions and/or fluid in the right minor fissure also be seen. In many cases, particularly in those with very advanced HF, the chest radiograph may be entirely clear, despite significant symptoms of dyspnea; the negative predictive value of chest radiography is too low to definitively exclude HF.¹⁶

The Electrocardiogram

The electrocardiogram (ECG) (see also Chapter 12) is a standard part of the initial evaluation of a patient with suspected HF, because it may provide important clues regarding incident HF, while also assisting in investigation of episodes of decompensation in previously diagnosed patients. In patients with HF, the ECG infrequently is normal but may show only nonspecific changes; thus, much as with chest radiography, the positive predictive value of ECG far surpasses its negative predictive value in this setting.

Sinus tachycardia secondary to sympathetic nervous system activation is seen with advanced HF or during episodes of acute decompensation. The presence of atrial arrhythmia on the ECG, as well as the ventricular response, may provide clues to the cause of HF and may also explain why a patient may have developed symptoms of decompensation; in addition, identifying atrial arrhythmia with a rapid ventricular response provides a target for therapeutic interventions.

The presence of increased QRS voltage may suggest left ventricular hypertrophy; in the absence of a previous history of hypertension, this finding might be the result of valvular heart disease or by hypertrophic cardiomyopathy, particularly if bizarre repolarization patterns are noted. If right ventricular hypertrophy is present, primary or secondary pulmonary hypertension should be considered. Low QRS voltage suggests the presence of an infiltrative disease or pericardial effusion. The presence of Q waves suggests that HF may be due to ischemic heart disease; new or reversible ST changes identify acute coronary ischemia, which may be present even when chest pain is absent. Indeed, because acute coronary ischemia is a leading cause of acutely decompensated HF, a 12-lead ECG should be immediately obtained in this setting, in order to exclude acute MI.

The intervals on the ECG may provide important information regarding causes of HF, as well as yielding information with respect to treatment strategy. Prolongation of the PR interval is common in patients in this setting and may be due to intrinsic conduction disease but also may be seen in patients with infiltrative cardiomyopathy. With the advent of cardiac resynchronization therapy (see Chapter 26), evaluation of the QRS complex has become a critical part of the clinical assessment in that it provides important information regarding the causes of HF, as well as providing pivotal information regarding the therapeutic approach. The QT interval often is prolonged in patients with HF, which may be due to electrolyte abnormalities, myocardial disease, or effects of commonly used drugs, such as antiarrhythmics. A lengthened QT interval may identify patients at risk for torsades de pointes and is therefore an important variable to consider with use of therapeutic agents with effects on ventricular repolarization.

Measurement of Blood Chemistry and Hematologic Variables

Patients with new-onset HF and those with acute decompensation of chronic HF should undergo testing with a laboratory panel that includes electrolytes, blood urea nitrogen, serum creatinine, hepatic enzymes, fasting lipid profile, thyroid-stimulating hormone, transferrin saturation, uric acid, a complete blood count, and a urinalysis. As discussed further on, the natriuretic peptides may be exceedingly useful for diagnosis as well as for prognostication. A test for human immunodeficiency virus infection or further screening for hemochromatosis is reasonable in selected patients, whereas diagnostic tests for rheumatologic diseases, amyloidosis, or pheochromocytoma are reasonable when suspicion exists for these diseases.

Abnormalities of sodium are common in patients with HF, particularly during periods of acute decompensation, and have substantial prognostic meaning.¹⁷ Studies have shown that hyponatremia (defined as serum sodium values below 135 mmol/L) may be found in up to 25% of patients with acutely decompensated HF, and hyponatremia also may be seen in patients with indolently worsening HF without obvious decompensation. Low sodium concentrations in HF may be due to worsening volume retention or may be related to the use of diuretics, including thiazides. Hyponatremia is associated with impaired cognitive and neuromuscular function, and when present and persistent, low sodium is strongly prognostic for longer hospital stay, as well as a high risk of death.¹⁷ Despite this correlation, strategies to correct serum sodium levels have not been shown to clearly improve the clinical course (see Chapter 24).¹⁸ Hypernatremia, although uncommon,

also is prognostic for death in patients with HF. Hypokalemia occurs commonly in those patients who are treated with diuretics. Besides increasing the risk of cardiac arrhythmias, low potassium also may lead to leg cramps and muscle weakness. Conversely, hyperkalemia is less common, and most often is due to effects of medications such as angiotensin-converting enzyme inhibitors or mineralocorticoid inhibition.

Abnormalities of renal function are common in patients with HF and may occur in association with renal congestion or inadequate cardiac output or as a consequence of comorbid conditions.^{19,20} In addition, HF therapies such as diuretics and angiotensin-converting enzyme inhibitors or angiotensin receptor blockers can increase blood urea nitrogen and creatinine. In this regard, abnormalities of renal function may have substantial effects on the ability to aggressively treat HF. Furthermore, abnormal renal function constitutes one of the more powerful prognostic variables gleaned from routine laboratory testing in HF. For these reasons, assessment of renal function should be performed as part of the initial evaluation of HF and then periodically repeated during follow-up care.

In patients hospitalized with acutely decompensated HF, registry data suggest that 60% to 70% have a reduced estimated glomerular filtration rate²¹; among such patients, the initial blood urea nitrogen and serum creatinine concentrations both are independently predictive of death.²² After hospitalization, an increase in serum creatinine by up to 0.3 mg/dL, which is similarly prognostic for death, may develop in approximately 30% of patients with acutely decompensated HF.^{19,23} The causes of this so-called cardiorenal syndrome are complex but include severe right heart congestion, increased intra-abdominal pressure (detectable by transduction of a Foley catheter in the bladder), and renal hypoperfusion from inadequate cardiac output.²⁴ When faced with worsening renal function, the clinician must perform a careful examination to assess volume status and tissue perfusion to decide on appropriate therapies to manage the situation. Although improvement in renal function may follow therapies relieving the severity of congestion, such a finding is still associated with poor long-term prognosis.

Diabetes mellitus is common in patients with HF, and hyperglycemia has emerged as a possible risk factor for adverse outcome in affected patients. Because diuretics can cause gout, measuring uric acid levels can help in patient management; elevated serum uric acid levels have been noted to be prognostic, and therapies to lower their concentration are now being studied to improve HF outcomes. Abnormalities in aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, bilirubin, or lactate dehydrogenase may occur in these patients as a consequence of hemodynamic derangements leading to hepatic congestion, or they may be due to medication effects; it is therefore important to monitor levels with periodic testing. An unexpected increase in prothrombin time in patients receiving warfarin therapy may be an early harbinger of decompensation, in that it may reflect impaired synthetic capacity of a congested liver. Albumin levels are an indication of the patient's nutritional status, and they may be depressed as a consequence of poor appetite or impaired absorption across an engorged bowel wall; hypoalbuminemia is prognostic for death in acute and chronic HF.²⁵

Hematologic abnormalities are exceedingly common in HF, affecting nearly 40% of the patients. Low hemoglobin levels have been associated with more severe HF symptoms, reduced exercise capacity and quality of life, and increased mortality.²⁶ Although anemia may be a consequence of chronic disease in patients with HF, a low hemoglobin level should trigger an evaluation to detect treatable causes, particularly iron deficiency. Increasing attention also has been given to the red cell distribution width as a prognostic variable in both acutely decompensated and chronic HF.²⁷ The white blood cell count with differential is helpful in detecting the presence of infection that is responsible for destabilizing a previously well-compensated patient and could provide a clue that HF is due to uncommon cause such as eosinophilic infiltration of the myocardium.

Biomarkers

Beyond standard laboratory testing, the measurement of newer biomarkers has emerged over the past decade as an important adjunct to the initial and subsequent evaluations of patients with suspected or proven HF. Biomarkers are now routinely used for distinguishing HF from other conditions and to establish the severity of the diagnosis and also are useful to provide important prognostic information in affected patients. Finally, considerable interest has emerged in

*Biomarkers in this category aid in elucidating the pathogenesis of HF.

†Biomarkers in this category provide prognostic information and enhance risk stratification.

‡Biomarkers in this category can be used to identify subjects at risk for HF.

§Biomarkers in this category are potential targets of therapy.

¶Biomarkers in this category are useful in the diagnosis of HF and in monitoring therapy.

From Braunwald E: Biomarkers in heart failure. *N Engl J Med* 358:2148, 2008.

determining the ability of biomarkers to guide therapy in both the acute and chronic settings. As shown in **Table 23-5**, Braunwald has proposed that HF biomarkers be divided into six distinct categories, with an additional one reserved for biomarkers that have not yet been classified.²⁸

As articulated by van Kimmenade and Januzzi,²⁹ clinically useful biomarkers of HF should be easily measured with high analytical precision, should reflect important processes involved in HF presence and progression, should not recapitulate clinical information already available at the bedside, and must provide clinically useful information for caregivers to more swiftly and reliably establish or reject a diagnosis, to more accurately estimate prognosis, or to inform more successful therapeutic strategies. Although only the natriuretic peptides have met these requirements, other promising biomarkers for use in HF assessment have been identified.

Natriuretic Peptides

The natriuretic peptides are useful biomarkers for HF diagnosis and estimation of HF severity and prognosis, and possibly for management of HF as well. The most commonly measured natriuretic peptides are B-type (i.e., brain) natriuretic peptide (BNP) and its amino-terminal cleavage pro-peptide equivalent, N-terminal pro-B-type natriuretic peptide (NT-proBNP); these two biomarkers are released from cardiomyocytes in response to stretch, and highly precise assays are available for their detection in blood (**see also Chapter 22**). In view of the preponderance of myocardium in the ventricles, BNP and NT-proBNP are held to reflect ventricular stretch and synthesized in response to wall stress. Atrial natriuretic peptide (ANP), another member of the class of natriuretic peptides, is synthesized and secreted from atrial tissue; a midregional pro-ANP (MR-proANP) assay is now available and appears to deliver results comparable to those for BNP and NT-proBNP assays in HF,³⁰ although data remain limited.

Owing to differences in their clearance, BNP and NT-proBNP have considerably different half-lives (BNP: 20 minutes; NT-proBNP: 90 minutes), so they circulate with very different concentrations in the bloodstream. Both natriuretic peptides have become an important part of the HF assessment; however, much as with any diagnostic test, it is essential to keep in mind the broad array of structural and functional reasons for BNP or NT-proBNP release in order to correctly interpret their values.³¹ Natriuretic peptide levels tend to increase progressively with worsening NYHA functional class and tend to be higher in HFrEF than in HFpEF, despite independent contributions of diastolic function to their concentrations. Patients with acutely decompensated HF most often have higher values for BNP and NT-proBNP compared with those with chronic stable HF; this is by no means a universal finding, however, and knowledge of an individual patient's natriuretic peptide value when stable may be useful to better interpret a change when a change in symptoms occurs.

When using BNP or NT-proBNP, the clinician should remember that beyond left ventricular systolic dysfunction, concentrations of both peptides are higher in patients with valvular heart disease, pulmonary hypertension, ischemic heart disease, atrial arrhythmias, and even pericardial processes such as constriction.³¹ Additionally, numerous relevant medical covariates with effects on natriuretic peptide values also must be kept in mind. For example, both BNP and NT-proBNP levels increase with age, thought to identify accumulating structural heart disease in older patients. Both natriuretic peptides are higher in patients with renal failure, partially reflective of slower clearance, but also similarly identifying heart disease in this population of patients with increased prevalence of cardiovascular risk factors. Elevated natriuretic peptide values also can be seen in hyperdynamic states, including sepsis. Patients who have right ventricular dysfunction as a result of pulmonary embolus may have elevated natriuretic peptide concentrations. Similarly, obesity is strongly linked to lower-than-expected BNP or NT-proBNP values, despite comparable or higher wall stress in heavier patients. In view of the common effect on BNP, NT-proBNP, and MR-proANP, this is not likely to reflect changes in clearance (because each type is cleared differently); rather, it is more likely to represent suppression of natriuretic peptide gene expression or post-translational modification.

Results of BNP or NT-proBNP, although useful, should always be interpreted in the context of sound clinical judgment, integrated with results of history, physical examination, and other modes of testing; these important biomarkers strongly supplement clinical judgment but should not replace it. So long as this principle is kept in mind, the natriuretic peptides have been shown to be quite useful to identify and exclude acutely decompensated HF in the emergency department, as well as more indolent HF in the outpatient setting. Suggested cut-off points for use of natriuretic peptides are shown in **Table 23-6**.³²

Pivotal data for BNP and NT-proBNP testing to diagnose acutely decompensated HF came from the Breathing Not Properly and ProBNP Investigation of Dyspnea in the Emergency Department (PRIDE) studies, respectively. In the Breathing Not Properly study, a BNP

TABLE 23-6 Suggested Cut-off Values for Clinical Applications of the Natriuretic Peptides

PEPTIDE	CUT-OFF VALUE	SENSITIVITY	SPECIFICITY	PPV	NPV
Exclusion of Acutely Decompensated HF					
BNP	<30-50 pg/mL	97%	*	*	96%
NT-proBNP	<300 pg/mL	99%	*	*	99%
MR-proANP	<57 pmol/L	98%	*	*	97%
Identification of Acutely Decompensated HF					
<i>Single cut-point strategy</i>					
BNP	≥100 pg/mL	90%	76%	79%	89%
NT-proBNP	≥900 pg/mL	90%	85%	76%	94%
MR-proANP	≥127 pmol/L	87%	79%	67%	93%
<i>Multiple cut-point strategy</i>

NPV = negative predictive value; PPV = positive predictive value.

concentration of 100 pg/mL was highly accurate for the diagnosis of acutely decompensated HF; in PRIDE, an NT-proBNP cut-off value of 900 pg/mL was comparable in performance to a BNP of 100 pg/mL. Subsequently, the International Collaborative of NT-proBNP Study (ICON) investigators showed that age stratification improved the positive predictive value of NT-proBNP in acutely dyspneic patients; as well, an NT-proBNP concentration below 300 pg/mL was useful to exclude acutely decompensated HF.³²

Knowledge of natriuretic peptide levels in the emergency department is associated with more rapid diagnosis, lower admission rate, shorter length of hospital stay, and reduced cost. Because clinical uncertainty in acute dyspnea is associated with worse prognosis, it is reassuring that natriuretic peptide testing is particularly useful in this complex situation.

For patients with less acute presentations of dyspnea in settings other than the emergency department, values of BNP or NT-proBNP are most often considerably lower. In evaluation of the dyspneic ambulatory patient, therefore, the optimized cut-off values from emergency department studies should not be used; lower values are mandatory, optimized for their negative predictive value to exclude (rather than to identify) HF (see Table 23-5).³² As shown by the ICON Primary Care group, age stratification again improves diagnostic accuracy in this setting. If values for a patient are found to be above such cut-offs, further diagnostic testing such as echocardiography probably is needed. Causes of falsely low BNP or NT-proBNP in the outpatient setting resemble those with acute dyspnea.

Natriuretic peptide levels provide useful prognostic information across all ACC/AHA stages of HF even when adjusted for important variables such as that gleaned from history, physical examination, echocardiography, or even cardiopulmonary exercise testing (CPX). Although a single natriuretic peptide measurement is prognostically

meaningful, serial follow-up measurements add incrementally important prognostic information. For example, in patients with acutely decompensated HF, those who do not show a robust reduction in BNP or NT-proBNP by the time of hospital discharge tend to have considerably higher rates of morbidity and mortality.³³ It has therefore been suggested that a BNP or NT-proBNP decrease of 30% or more by hospital discharge is desirable. Similarly, in so-called ambulatory HF, chronically elevated or rising natriuretic peptide values identify a particularly high-risk patient population. Because HF therapies may lower concentrations of BNP and NT-proBNP, this link between natriuretic peptides and prognostic monitoring has led to the concept of their use to specifically "guide" HF therapy.³⁴ The results of trials examining natriuretic peptide-guided HF care have been conflicting (Table e23-1); recent results, however, support the approach, particularly when low BNP or NT-proBNP targets are used, and when significant therapy adjustment is implemented in response to recognition of elevated natriuretic peptide values.³⁴

Other Biomarkers

Other promising biomarkers for use in patients with HF have been identified, and some are clinically available (see Table 23-5). In general, newer biomarkers for HF have been developed to supplement the natriuretic peptides for prognostication. Although most have not yet achieved the prerequisite data to justify widespread use, a few promising biomarkers bear mention.

Circulating concentrations of soluble ST2 (a member of the interleukin receptor family) have been shown to be strongly linked to progressive HF and death in patients across the four ACC/AHA stages of HF.²⁹ Originally identified in a basic science model of mechanotransduction,

TABLE e23-1 Comparison of Results of Biomarker-Guided Heart Failure Studies*

STUDY	BIOMARKER	TARGET NP?	SIGNIFICANT NP LOWERING?	MORE AGGRESSIVE CARE IN NP ARM?	OUTCOME
STARBRITE ^a	BNP	High	No	Yes	—

ST2 plays a pivotal role in the formation of fibrosis in the heart; elevated concentrations of ST2 are therefore associated with progressive cardiovascular dysfunction, remodeling, and risk for death. Soluble ST2 concentrations are additive (and superior) to natriuretic peptides for prognostication, are useful in both HFrEF and HFpEF, and are similar to natriuretic peptides in capacity to induce changes after HF therapies; in patients with both acutely decompensated and chronic HF, a chronically elevated or rising ST2 value strongly predicts adverse outcome. Of note, among apparently normal patients in a population-based analysis, ST2 values predicted future HF, beyond other biomarkers such as BNP as well as echocardiographic parameters.³⁵ This finding implies that the biochemical changes of ventricular remodeling may be detectable well before conventional biomarkers or imaging are abnormal.

Galectin 3 is another novel biomarker of tissue fibrosis. It is produced by a variety of cell types, including activated macrophages following tissue injury and is strongly associated with increased myocardial collagen formation. When measured clinically, elevated galectin 3 values predict not only adverse outcomes in patients with HF associated with both HFrEF and HFpEF but also onset of HF in apparently normal patients, similar to ST2.²⁹

The myofibrillar proteins *troponin T* and *I* are indicators of cardiomyocyte injury and may be elevated in patients with HF in the absence of an acute coronary syndrome or even significant coronary artery disease. Although an elevated troponin value does not specifically identify myocardial necrosis resulting from coronary artery disease per se, in view of the importance of acute MI in the triggering of acutely decompensated HF, a troponin should always be measured in this setting, albeit interpreted with caution. Elevated troponin concentrations are prognostic for onset of HF and independently predict increased mortality across the HF spectrum. With the emergence of highly sensitive troponin assays, even more patients may be found to have elevated concentrations of these important predictors of risk.³⁶

Other novel biomarkers are emerging and may have a role in the comprehensive evaluation of the patient with HF; many of these novel markers reflect systemic stress or disarray of organs outside of the heart. For example, the midregional fragment of proadrenomedullin is a biomarker reflective of vascular and systemic stress and is powerfully prognostic for short-term adverse outcome (see also Chapter 22).³⁰ In similar fashion, growth differentiation factor-15, another marker of cardiovascular stress, not only strongly predicts outcomes in established HF but also may be prognostic for new-onset HF in apparently well subjects.³⁵ The C-terminal fragment of proavopressin (also known as copeptin) provides an indirect means by which to measure the biologically unstable parent hormone from which it is derived; values of copeptin are prognostic in HF but intriguingly are not directly associated with serum sodium values in this setting.²⁹ Finally, novel biomarkers of renal dysfunction are emerging as strong predictors of cardiovascular risk beyond the standard measures of blood urea nitrogen or serum creatinine. Cystatin C (a ubiquitous protein found in all nucleated cells whose clearance is directly related to glomerular filtration) and beta trace protein are two renal function markers whose values are tightly related to outcomes in HF, and neutrophil gelatinase-associated lipocalin, *N*-acetyl- β -D-glucosaminidase, and kidney injury molecule-1 are promising biomarkers of acute renal injury for which values rise well before renal function is perceived to be worsening and impart important prognostic information in patients with HF.²⁰

Ultimately, for the comprehensive evaluation of HF, it seems likely that a combination or panel of biomarkers will prove to be the most useful way of assessing prognosis.

RISK SCORING FOR PROGNOSIS

During initial and subsequent evaluation of the patient with HF, the clinician should routinely assess the potential for adverse outcome. Besides biomarker testing, a number of validated methods for risk stratification in HF exist, including a variety of multivariable clinical risk scores for use in both ambulatory and hospitalized patients. One well-validated risk score, the Seattle Heart Failure model, is available as an Internet-based application (www.seattleheartfailuremodel.org) and has been shown to provide robust information regarding risk of death in patients with ambulatory HF.³⁷ For patients hospitalized with acute decompensation symptoms, the model developed by the Acute Decompensated Heart Failure National Registry (ADHERE) incorporates three routinely measured variables upon hospital admission

(systolic blood pressure, blood urea nitrogen, and serum creatinine) and partitions subjects into categories with a 10-fold difference in risk (from 2.1% to 21.9%).²² Of importance, clinical risk scores have not performed as well in estimating risk of hospital readmission. For this purpose, biomarkers may be of more use.

RIGHT-HEART CATHETERIZATION

Measurement of intracardiac pressures and hemodynamics as part of the diagnostic work-up or for guiding therapy is less commonly performed now than in the past, because biomarkers and noninvasive imaging techniques provide much of the information that was previously available only with heart catheterization. Nonetheless, inasmuch as right-heart catheterization (see Chapter 19) affords unequivocal assessment of hemodynamics and filling pressures, it is particularly useful in cases involving uncertainty about the cause of a patient's symptoms and in situations necessitating precise measurements to guide therapy or decision making (e.g., selection of patients for heart transplantation). As well, right-heart catheterization is of value (and should be considered) in those with HF complicated by clinically significant hypotension, systemic hypoperfusion, dependence on inotropic infusions, or persistently severe symptoms despite adjustment of recommended therapies.

An invasive assessment with right-heart catheterization is important to assess the pulmonary vascular resistance, a necessary part of the evaluation for heart transplantation. When pulmonary artery pressures are found to be elevated, response to pulmonary arterial vasodilating agents can be determined in this context and provides important information determining whether a patient with pulmonary hypertension will be an acceptable candidate for cardiac transplantation. In addition, obtaining the pulmonary artery wedge pressure is useful for assessing volume status. The pulmonary artery wedge pressure usually estimates the left ventricular end-diastolic pressure if no obstruction to flow between the left atrium and left ventricle exists. Although determination of hemodynamic variables at rest suffices in most patients, in some cases exercise helps to reveal the presence and/or magnitude of abnormal intracardiac pressures and flow. Pulmonary hypertension, for example, can be highly dynamic, and exercise measurements may be needed.

Use of hemodynamic monitoring to guide therapy was evaluated in patients with advanced HF in the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial.³⁸ The results did not show any clear benefit on morbidity and mortality of pulmonary artery pressure-guided management compared with careful clinical assessment. The failure to affect post-discharge outcomes appears to be related to the fact that the hemodynamic improvements that were obtained during hospitalization reverted back toward baseline within a relatively short period of time. Consequently, "tailored therapy" of HF is used less commonly now than in the past but still has a role, particularly in patients with HF complicated by systemic hypoperfusion.

ENDOMYOCARDIAL BIOPSY

The role of endomyocardial biopsy for evaluating patients with HF also is discussed in Chapter 67. In general, biopsy of the myocardium is performed if a disorder with a unique prognosis or one that would respond to a specific treatment regimen is suspected and the diagnosis cannot be made by conventional methods. The incremental diagnostic, therapeutic, and prognostic benefits offered by the information obtained from a biopsy must be weighed against the risks of the procedure.

DETECTING COMORBID CONDITIONS

The incidence of HF rises sharply from the sixth decade onward, which is coincident with the time when other chronic diseases begin

to manifest. In addition, many of the conditions leading to the development of HF (e.g., diabetes, hypertension, atherosclerosis) affect organs other than the heart. Thus comorbid diseases are quite common in patients with HF and have a profound effect on the course of affected patients: A substantial percentage of hospitalizations incurred by patients with HF are in fact non-HF-related, and hospital admission is not precipitated by a cardiac condition in more than half of the cases.³⁹

Additional information on this topic is presented in the online supplement for this chapter (Comorbid Conditions and Heart Failure).

ASSESSMENT OF QUALITY OF LIFE

HF has a profound effect on quality of life, and poor health-related quality of life is a powerful predictor of adverse prognosis in affected patients. Determinants of poor quality of life in HF include female sex, younger age, higher body mass index (BMI), and more severe symptoms, as well as the presence of depression and sleep apnea.⁴⁰ Improved quality of life has been reported after cardiac resynchronization therapy or in disease management programs with aggressive care. In view of its importance, at the initial and subsequent visits, consideration should be given for quality of life assessment, whether accomplished by taking a standard history or through use of validated tools for its estimation, such as the Kansas City Cardiomyopathy Questionnaire or the Minnesota Living with Heart Failure Questionnaire.

CARDIOPULMONARY EXERCISE TESTING

Exercise intolerance is a prime symptom of HF. Despite this fact, quantification of exercise tolerance is imprecise; standard approaches such as use of the NYHA criteria or the 6-minute walk test are subjective and insensitive measures of functional capacity. Additionally, the 6-minute walk test does not reveal how close the patient may be to maximal capacity for exercise, does not discriminate between the causes of impaired exercise capacity (e.g., cardiac, pulmonary, orthopedic) and poor motivation, and does not account for the effects of (de)conditioning and/or age. When more precise information is needed, cardiopulmonary-specific exercise testing often is used, because it allows for identification of causes of exercise intolerance and quantification of exercise capacity and delivers important physiologic information not routinely available from standard stress testing.⁴¹

CPX is performed using treadmill or cycle exercise, continued to symptom limitation. Analysis of gas exchange at rest, during exercise, and in the recovery phase after exertion is performed, and measures of oxygen uptake ($\dot{V}O_2$), expiratory ventilation (\dot{V}_E), and carbon dioxide output ($\dot{V}CO_2$) are generated, typically expressed as a ratio of their slopes. The maximum $\dot{V}O_2$ is the standard expression of capacity for endurance, and determination is based on the Fick equation, which states that $\dot{V}O_2 = \text{cardiac output} \times [\text{oxygen content}_{\text{arterial}} - \text{oxygen content}_{\text{venous}}]$. Thus $\dot{V}O_2$ is a direct function of cardiac output, and indeed very strong associations are established between maximal $\dot{V}O_2$, cardiac output, and risk for death. The $\dot{V}_E/\dot{V}CO_2$ slope is an expression of efficiency of pulmonary CO_2 clearance during exercise and also has been suggested to be powerfully prognostic. These variables often are used in conjunction with each other in the assessment of advanced HF.

Use of CPX is a standard part of the routine evaluation before heart transplantation; moderate to severely reduced maximal $\dot{V}O_2$ values (e.g., $<14 \text{ mL O}_2 \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) often are used as a prognostic threshold in this setting, whereas maximal $\dot{V}O_2$ values below $10 \text{ mL O}_2 \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ are considered severely reduced and are particularly prognostic when the $\dot{V}_E/\dot{V}CO_2$ slope is 45.0 or greater. Many favorable therapies for HF such as with certain drugs, cardiac resynchronization therapy, or exercise may result in improvement in CPX parameters; however, this is not universal. For example, beta blocking agents have significant influence on survival but do not significantly improve maximal

$\dot{V}O_2$. Thus, because beta blockers improve prognosis across all ranges of maximal $\dot{V}O_2$, aggressive use of these agents may necessarily result in a lower optimal cut-point than below $14 \text{ mL O}_2 \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ for referral for cardiac transplantation. Although CPX is most validated in HFrEF, it appears to be of prognostic value in HFpEF, although data are more limited.

IMAGING MODALITIES USEFUL IN DIAGNOSIS AND MANAGEMENT OF HEART FAILURE

Noninvasive cardiac imaging serves a vital role in the assessment of patients with HF and is essential for determining whether the patient should be classified as having HFpEF or HFrEF. Imaging may help confirm the diagnosis of HF by assessing the presence and severity of structural and functional changes in the heart, provide clues about the etiology of cardiac dysfunction (i.e., congenital heart disease, valvular abnormalities, pericardial disease, coronary artery disease), risk stratify patients, and possibly guide treatment strategies. Imaging modalities also can be used to help assess the efficacy of therapeutic interventions, provide ongoing prognostic information, and guide further treatment. The primary noninvasive cardiac imaging modalities used to evaluate patients with HF are echocardiography (Chapter 14), magnetic resonance imaging (MRI) (Chapter 17), computed tomography (CT) (Chapter 18), and nuclear imaging, including single photon emission computed tomography (SPECT) and positron emission tomography (PET) techniques (Chapter 16). Imaging modalities often provide complementary data, and each has the capacity to contribute unique information in individual patients. Although the initial evaluation of a patient with newly diagnosed HF should include a transthoracic echocardiogram, further imaging with MRI, CT, and/or nuclear techniques may be considered, depending on the need to further address questions regarding cardiac structure and function, etiology, and issues such as the potential for reversibility of systolic dysfunction with revascularization. The specific indications for and advantages of each of these imaging modalities are summarized in Figure 23-3 and Table e23-2.

Echocardiography

Transthoracic echocardiography (see also Chapter 14) is an important part of the evaluation of HF,⁴² can be performed without risk to the patient, does not involve radiation exposure, and can be performed at the bedside if necessary. It is particularly well suited for evaluating the structure and function of both the myocardium and heart valves and providing information about intracardiac pressures and flows.

ARVC = arrhythmogenic right ventricular cardiomyopathy; CAD = coronary artery disease; CMP = cardiomyopathy; CMR = cardiac magnetic resonance [imaging]; Echo = echocardiography; HCM = hypertrophic cardiomyopathy; MDCT = multiple-detector computed tomography.

Modified from McMurray JJ, Adamopoulos S, Anker SD, et al: ESC guidelines for the diagnosis and treatment of acute and chronic heart failure 2012: The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012 of the European Society of Cardiology. Developed in collaboration with the Heart Failure Association (HFA) of the ESC. *Eur J Heart Fail* 14:803, 2013.

For patients with HFrEF, left ventricular volumes and systolic function can be assessed semiquantitatively, or quantified using the biplane method and the modified Simpson's rule. Information about the morphology and relative sizes of the cardiac chambers may suggest specific diagnoses. For example, concentric left ventricular hypertrophy with severe biatrial enlargement raises the possibility that HF is due to an infiltrative process such as amyloidosis, particularly in the absence of a previous diagnosis of hypertension. Diastolic function is assessed using Doppler measurements, including analyses of the mitral valve inflow pattern (early [E] and atrial [A] waveforms), tissue velocities at the mitral valve annulus, pulmonary vein flow, and the left atrial volume indexed to body surface area (see Chapters 14 and 27). Diastolic dysfunction can be further classified as grades I to III based on the foregoing measurements, with incremental prognostic importance in HF as worsening grades of diastolic dysfunction are noted. Pulmonary hypertension in patients without significant systolic dysfunction or pulmonary disease suggests that diastolic dysfunction may be present.

Another advantage of echocardiography is the ability to noninvasively estimate right-sided heart pressures. For example, right atrial pressures are estimated by the inferior vena cava (IVC) diameter and the relative change in diameter on inspiration. Normal IVC diameter and inspiratory collapse of at least 50% are associated with normal right atrial pressures, whereas increased IVC diameter and smaller inspiratory changes indicate elevated right atrial pressure.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) (see also Chapter 17) provides high-quality imaging of the heart and involves no radiation exposure, which is a significant advantage over CT. Diagnostic images can be obtained in nearly all patients, and unlike with echocardiography,

images can be obtained in arbitrary tomographic planes. MRI is excellent for evaluating cardiac morphology, chamber sizes, and cardiac function. Using different pulse sequences with and without gadolinium contrast, MRI can characterize myocardial tissue and assess myocardial viability. Cardiac MRI can distinguish ischemic from nonischemic cardiomyopathies based on the pattern of delayed gadolinium enhancement from T1-weighted images: Ischemic cardiomyopathies usually show characteristic subendocardial enhancement at the sites of previous infarctions, whereas nonischemic dilated cardiomyopathies most commonly exhibited either no enhancement, mid-wall enhancement, or other patterns, depending on the etiology⁴³ (Fig. 23-4). Additionally, MRI is extremely useful to identify the presence of myocarditis⁴⁴ and may be similarly helpful in the diagnosis of specific cardiomyopathies such as infiltrative processes or left ventricular noncompaction. A major limitation is that the current implanted pacemakers or defibrillators are not safe to undergo MRI, although this limitation may be overcome with the emergence of MRI-compatible devices.

Cardiac Computed Tomography

The current role of cardiac CT (see also Chapter 18) in HF is mainly to help determine whether or not obstructive coronary artery disease is present by means of CT angiography,⁴⁵ an important application, particularly for patients with lower likelihood of coronary artery disease. Emerging applications of CT angiography may be to assist in assessment of coronary venous anatomy before cardiac resynchronization therapy (CRT) lead placement. Recent advances in CT technology have led to less radiation exposure; however, cardiac CT angiography still involves administering iodinated contrast, a concern in patients who are at risk for development of nephrotoxicity.

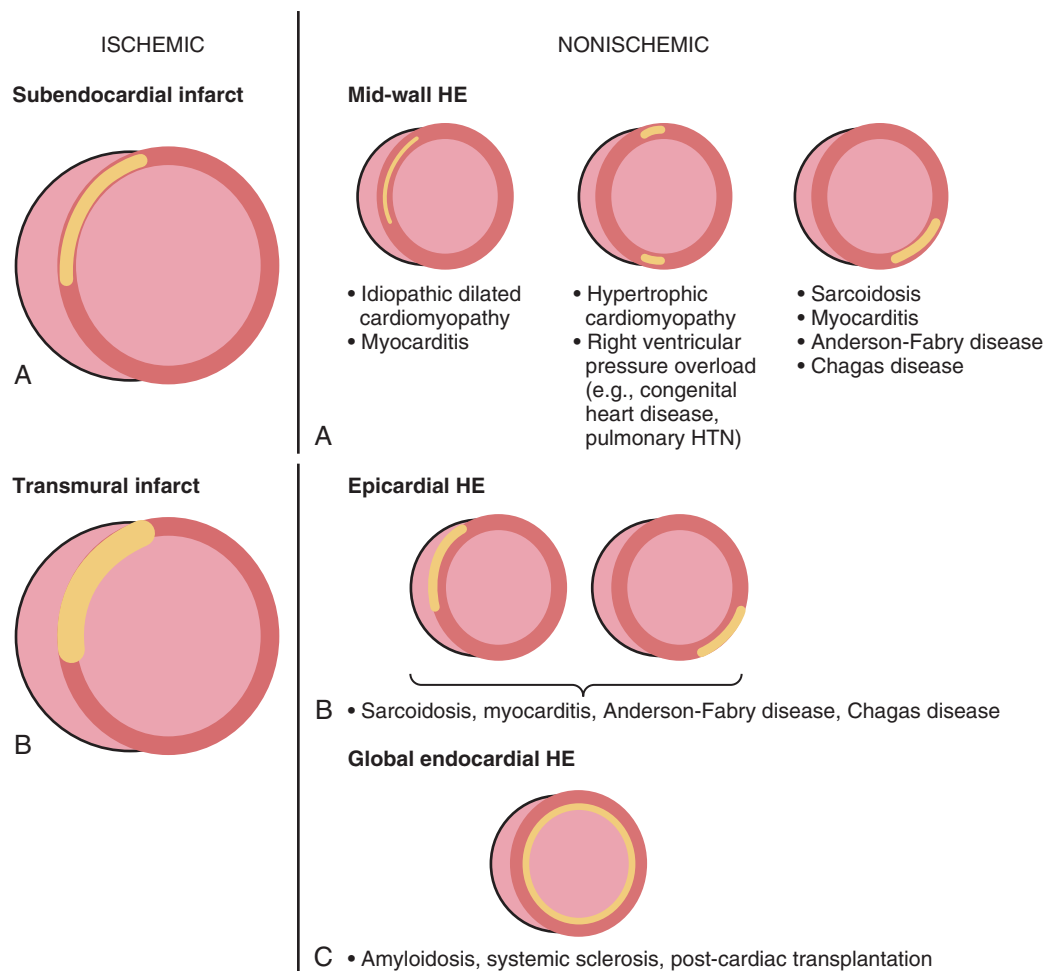

FIGURE 23-4 Patterns of hyperenhancement (HE) with MRI in various disease states, with localization for ischemic versus nonischemic lesions. HTN = hypertension. (Modified from Mahrholdt H, Wagner A, Judd RM, et al: Delayed enhancement cardiovascular magnetic resonance assessment of non-ischaemic cardiomyopathies. *Eur Heart J* 26:1461, 2005.)

COMORBID CONDITIONS AND HEART FAILURE

Many of the conditions leading to the development of HF (e.g., diabetes, hypertension, atherosclerosis) affect organs other than the heart. Comorbid conditions are therefore quite common in HF and have a profound effect on the clinical course: Recent registry data indicate that a substantial percentage of required hospitalizations in patients with HF are non-HF-related and not precipitated by a cardiac event.

Several comorbid conditions associated with HF bear mention. *Atrial arrhythmias* (see also Chapters 37 and 38) are common in patients with HF and have a considerable effect on stability; accordingly, atrial fibrillation should be assiduously sought in patients with decompensation that is not easily explained. *Depression* is very common in patients with HF and leads to decreased quality of life and worse clinical outcomes (see Chapter 86).¹ Although treatment of depression in HF has not yet been shown to improve prognosis,

there is no mistaking the benefit on quality of life from its treatment. Finally, *sleep apnea* frequently is overlooked during the clinical assessment but has been reported in greater than 50% of patients with HF. Recognition of the obstructive form of sleep apnea is of great importance, because appropriate therapy can have a significant effect on the patient's symptomatic status and also improve ejection fraction in patients with systolic dysfunction (see Chapters 25 and 76).² Clues to the presence of sleep apnea come from the patient's body habitus (e.g., obesity and/or a thick neck) and a history of snoring and/or daytime somnolence. Often the spouse or significant other provides the description of these symptoms and the presence of apneic periods and Cheyne-Stokes respirations occurring while the patient sleeps.

Nuclear Imaging

A wide array of nuclear imaging techniques have been developed for the investigation of HF (see also Chapter 16). In particular, SPECT and PET technologies are well suited for assessing myocardial ischemia and viability and for evaluating myocardial function. The use of nuclear imaging to determine myocardial viability is discussed in Chapter 16.

SUMMARY AND FUTURE PERSPECTIVES

As treatment options for HF continue to evolve, the emphasis will be on more rapid, accurate, and cost-effective assessment of patients, with the goal of providing unambiguous information about the presence, severity, and cause of HF. New insights into the biology of cardiac dysfunction are likely to lead to the development of therapeutic approaches that are specific to the underlying etiology. Continued advances in the use of biomarkers and imaging techniques to diagnose, stage, and determine the underlying cause of HF will be needed to meet these future demands. Even as these diagnostic modalities increase in their precision and accuracy, the information obtained through the history and physical examination will remain at the core of our understanding of how to use these tests most judiciously and how to treat patients most effectively.

Acute heart failure (AHF) is among the most common causes for hospitalization in patients older than 65 years of age in the developed world. In the United States alone, approximately 3 million patients are hospitalized each year with a primary or secondary diagnosis of heart failure, and AHF contributes to more than 7 million hospital days annually.¹ The number of hospitalizations for heart failure has tripled during the past three decades (**Fig. 24-1**) and is projected to continue to increase because of a convergence of several epidemiologic trends: the aging of the population, against a background of the age-related incidence of heart failure; the reduction in hypertension-related mortality and the greatly improved survival after myocardial infarction, resulting in more patients living with chronic left ventricular (LV) dysfunction; and the availability of effective therapy for prevention of sudden death. Previously considered part of the clinical history of chronic heart failure, AHF is increasingly recognized as a distinct disorder with unique epidemiology, pathophysiology, treatments, and outcomes.

EPIDEMIOLOGY

Nomenclature and Definition

A variety of overlapping terms have been used to characterize AHF in the literature, including “acute heart failure syndromes” (AHFSs), “acute(ly) decompensated heart failure” (ADHF), “acute decompensation of chronic heart failure” (ADCHF), and “hospitalization for heart failure” (HHF). Although none of these is universally accepted, the term *acute heart failure* is used in this chapter for consistency and simplicity. Broadly speaking, AHF can be defined as the new onset or recurrence of symptoms and signs of heart failure requiring urgent or emergent therapy and resulting in seeking unscheduled care or hospitalization. Although the designation “acute” in the nomenclature suggests a sudden onset of symptoms, many patients may have a more subacute course, with gradual worsening of symptoms that ultimately reach a level of severity sufficient to seek unscheduled medical care.

Scope of the Problem

AHF represents a major burden in the developed world. In the United States, heart failure is the primary diagnosis for more than 1 million hospitalized patients annually, and a secondary diagnosis in

an additional 2 million hospitalizations.¹ Even greater numbers of hospitalizations are reported in Europe.² The annual direct and indirect costs associated with heart failure approach \$40 billion in the United States, and most of these expenditures are related to the costs of hospitalizations. As noted previously, the overall number of hospitalizations for heart failure continues to grow as a consequence of the aging of the population, improved survival after acute myocardial infarction, and effective prevention of sudden cardiac death. Recent data, however, suggest that the age-adjusted rate of hospitalization for heart failure may have begun to decrease with improvements in chronic heart failure therapy. In a study using U.S. Medicare claims data from 1998 to 2008, age-related incidence of hospitalization for heart failure declined for all race and gender groups.³ Similar data have been published in several countries in Europe.⁴ Despite these potentially encouraging trends, it appears likely that heart failure–related hospitalization will be a major clinical and economic problem for health care systems for the foreseeable future. A major breakthrough in the understanding of the epidemiology, clinical characteristics, and outcomes of patients with AHF has been the development of large, relatively unselected registries of AHF cases throughout the world, which have provided a “real world” perspective on the epidemiology and outcomes of this clinical syndrome (**Table 24-1**).

Preserved Versus Reduced Ejection Fraction

As with chronic heart failure, recent decades have seen increasing recognition of the epidemiologic importance of heart failure with normal or near-normal systolic function, so-called *heart failure with preserved ejection fraction* (HFpEF) (**see also Chapter 27**). On the basis of the registry data, 40% to 50% of patients hospitalized have HFpEF.⁵ The unexpectedly high prevalence of HFpEF in AHF registries exemplifies the way registry data can better inform understanding of the epidemiology of a clinical problem compared with clinical trials, which have tended to focus on younger patients with impaired systolic function and fewer comorbid diseases. Compared with patients with heart failure and low ejection fraction, those with HFpEF are more likely to be older, to be female, and to have a history of hypertension, while being less likely to have underlying coronary artery disease.⁵ Although these differences are notable in large epidemiology studies, it is important to recognize that individual patient characteristics, clinical presentation, and physical examination are not sufficient to distinguish these entities at the bedside without

formal assessment of ejection fraction. The in-hospital mortality for patients with HFpEF appears to be lower than that for patients with depressed LV ejection fraction (LVEF), but postdischarge rehospitalization rates are similarly high for both groups. Patients with AHF and HFpEF are more likely to be rehospitalized for and to die from non-cardiovascular causes than patients with AHF and reduced ejection fraction, reflecting their more advanced age and greater burden of comorbidity.⁶

Age, Race, and Sex

Significant differences in the epidemiology of AHF, based on age, race, and sex, have been recognized. AHF disproportionately affects elderly people, with a mean age of 75 years in large registries. In clinical trial populations, by contrast, the mean age often is substantially lower. AHF affects men and women almost equally, but important differences by sex are recognized. In the ADHERE registry, women admitted for AHF were older than men (74 versus 70 years), and more frequently had preserved systolic function (51% versus 28%).⁷ Differences in ethnic groups have been studied most extensively in the United States and have focused primarily on differences between African American and white patients. In the Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) registry, African American patients admitted with AHF were younger (64 versus 75 years), more likely to have LV systolic dysfunction (57% versus 51%) with a lower mean ejection fraction (35% versus 40%), hypertensive cause for heart failure (39% versus 19%), renal dysfunction, and diabetes, compared with the non-African American group.⁸ Lower crude mortality rates have been reported for African Americans than for non-African American patients, but when adjustments are made for these differences in comorbidity and age, mortality rates are similar.

Comorbid Conditions

Concomitant diseases are very common in patients hospitalized with AHF, reflective of the elderly population. These comorbid conditions not only represent diseases that are risk factors for the development of heart failure but also can complicate diagnosis and management. Hypertension is the most prevalent of the concurrent conditions, present in approximately two thirds of the patients (see also [Chapters 43 and 44](#)); coronary artery disease is present in approximately half and dyslipidemia more than one third (see also [Chapter 54](#)).^{9,10}

Other conditions that are the result of the vascular injury produced by these diseases, such as stroke, peripheral vascular disease, and chronic renal insufficiency, also are very common in patients with AHF. Diabetes mellitus is present in greater than 40% of U.S. patients, most likely related to increasing incidence of obesity, and in 27% to 38% of patients in Europe. Chronic obstructive pulmonary disease (COPD) also is present in approximately 25% to 30%, which confounds the presenting symptoms of dyspnea and is associated with lower use of evidence-based therapy.¹¹ Atrial fibrillation appears to be more common in Europe (reported frequency of up to 42%, compared with 31% in U.S. patients with AHF), and can both precipitate AHF and complicate its management.¹²

PATHOPHYSIOLOGY

AHF is not a single disease but a heterogeneous clinical syndrome. Accordingly, the pathophysiology of AHF is complex and highly variable, with many overlapping pathogenic mechanisms that may be operative in a given clinical scenario to a greater or lesser degree. This fundamental heterogeneity complicates the attempt to create a simple and unified conceptual model. One potentially useful framework for understanding of the pathophysiology of AHF is to consider it as the result of the interaction of underlying substrate, initiating mechanisms or triggers, and amplifying mechanisms, all of which contribute to a common set of clinical signs and symptoms (primarily related to congestion or end-organ dysfunction, or both) that define AHF (Fig. 24-2). In this context, *substrate* refers to underlying cardiac structure and function. The underlying substrate may be one of normal ventricular function, as in patients without a previous history of heart failure in whom AHF develops because of sudden changes

in ventricular function from an acute insult such as myocardial infarction or acute myocarditis. Alternatively, some patients may have no previous history of heart failure but exhibit an abnormal substrate (e.g., those with stage B heart failure associated with asymptomatic LV dysfunction) with a first presentation of heart failure (de novo heart failure). Finally, in most patients with AHF, the original substrate is one of chronic compensated heart failure, followed by decompensation with development of AHF.

Initiating mechanisms vary according to, and interact with, the underlying substrate and may be cardiac or extracardiac. For patients with normal substrate (normal myocardium), a substantial insult to cardiac performance (e.g., acute myocarditis) is required to lead to the clinical presentation of AHF. For patients with abnormal substrate at baseline (e.g., asymptomatic LV dysfunction), smaller perturbations (e.g., poorly controlled hypertension, atrial fibrillation, or ischemia) may precipitate an AHF episode. For patients with a substrate of compensated or stable chronic heart failure, medical or dietary noncompliance, drugs such as nonsteroidal anti-inflammatory agents or thiazolidinediones, and infectious processes all are common triggers for decompensation.

Regardless of the substrate or initiating factors, a variety of “amplifying mechanisms” perpetuate and contribute to the episode of decompensation. These include neurohormonal and inflammatory activation, ongoing myocardial injury with progressive myocardial dysfunction, worsening renal function, and interactions with the peripheral vasculature, all of which may contribute to the propagation and worsening of the AHF episode.

Congestion

Systemic or pulmonary congestion, most often the result of a high LV diastolic pressure, dominates the clinical presentation in most

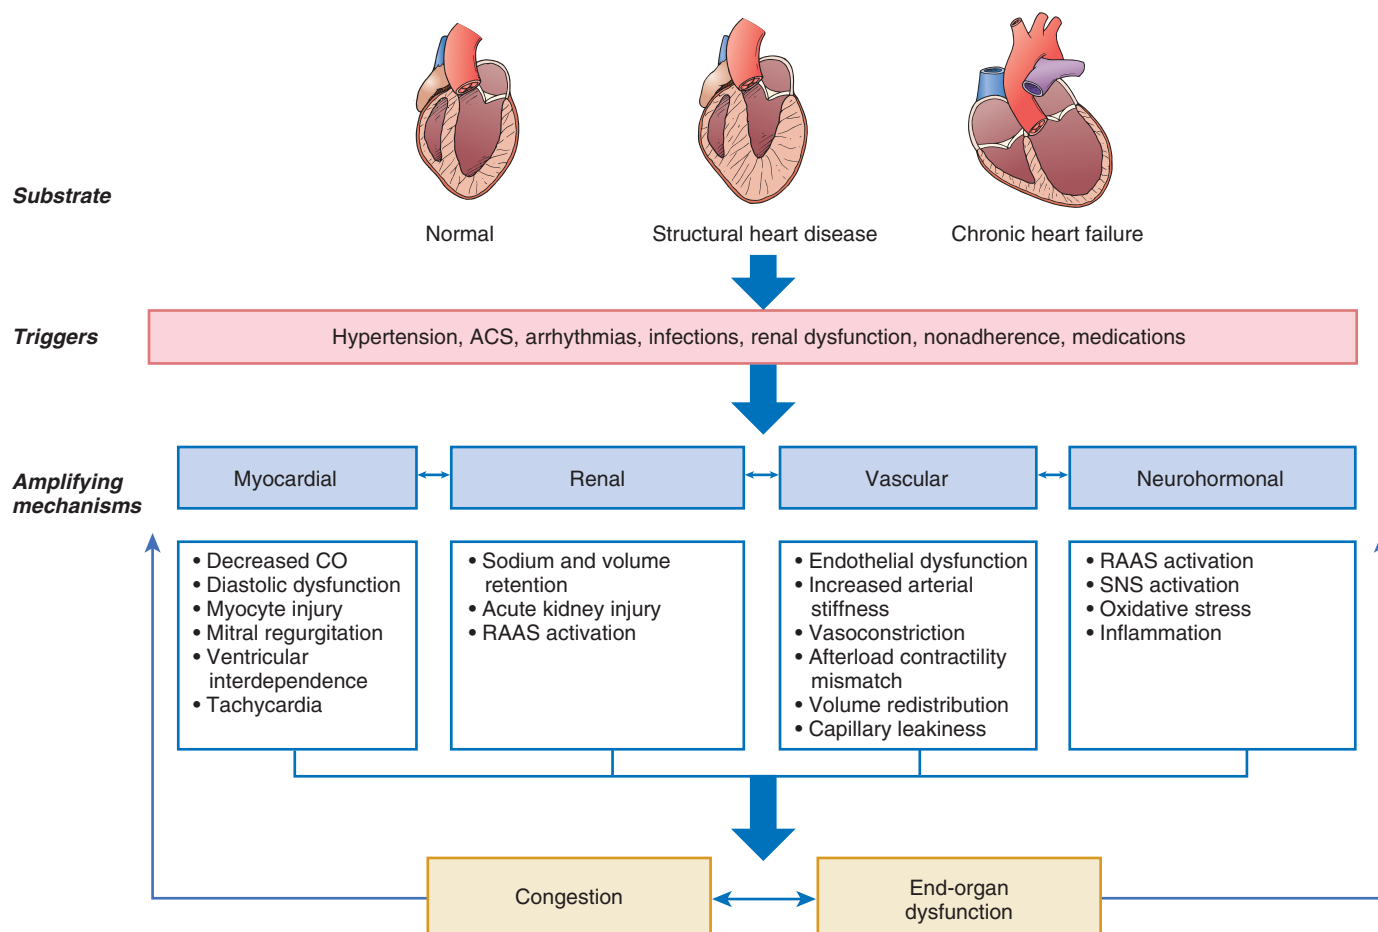

FIGURE 24-2 A schematic representation of the pathophysiology of AHF. ACS = acute coronary syndrome; CO = cardiac output; RAAS = renin-angiotensin-aldosterone system; SNS = sympathetic nervous system.

patients hospitalized for AHF. In this sense, congestion can be seen as a final common pathway by which mechanisms described in this section produce clinical symptoms leading to hospitalization. A simplified view of AHF pathophysiology is that gradual increases in intravascular volume lead to symptoms of congestion and clinical presentation, and normalization of volume status with diuretic therapy results in restoration of homeostasis. Although this mechanism may be operative in some patients (particularly those with frank noncompliance with sodium restriction or diuretic therapy), this model is a vast oversimplification. Congestion often occurs even in the absence of nonadherence, and the same degree of nonadherence may not lead to decompensation in a given patient. Although some data suggest that increases in body weight often precede decompensation and hospitalization for heart failure, careful studies using implantable hemodynamic monitors suggest that increases in invasively measured LV filling pressures can occur without substantial changes in body weight.¹³ These observations have led to increasing interest in the concept of volume redistribution rather than volume retention as a mechanism of decompensation in heart failure (discussed in more detail in a later section, **Vascular Mechanisms**).

One potentially important concept is the distinction between *clinical congestion* and *hemodynamic congestion*. Although patients present with signs and symptoms of systemic congestion such as dyspnea, rales, elevated jugular venous pressure, and edema, this state often is preceded by so-called hemodynamic congestion, defined as high LV diastolic pressures without overt clinical signs. Similarly, clinical congestion may resolve with treatment but hemodynamic congestion may persist, leading to a high risk of rehospitalization. It has been postulated that hemodynamic congestion may contribute to the progression of heart failure because it may result in wall stress, as well as in renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system (SNS) activation. These effects may trigger a variety of molecular responses in the myocardium, including myocyte loss and increased fibrosis. Concomitant abnormal processing of the natriuretic peptides, which are the intrinsic counterregulatory hormones in heart failure, leads to diminished biologic activity in patients with advanced disease.¹⁴ In addition, elevated diastolic filling pressures may decrease coronary perfusion pressure, resulting in subendocardial ischemia with further exacerbation of cardiac dysfunction. Increased LV filling pressures also can lead to acute changes in ventricular architecture (resulting in a more spherical shape), contributing to worsening mitral regurgitation. These mechanisms also play an important role in pathologic remodeling of the ventricle, a chronic process that may be accelerated by each episode of decompensation. Consistent with this paradigm is the well-established clinical observation that each hospitalization for AHF heralds a substantial worsening of the long-term prognosis, an effect that appears additive with recurrent hospitalizations.¹⁵ Data from studies with implantable hemodynamic monitors have confirmed that chronically elevated filling pressures (i.e., hemodynamic congestion) are associated with increased risk of future events.¹⁶ Although congestion is widely recognized at the most common aspect of AHF presentation, only recently has there been a formal attempt to better assess and quantitate congestion in heart failure.¹⁷

Myocardial Function

Although a variety of extracardiac factors play important roles in AHF, impairments of cardiac function (systolic, diastolic, or both) remain central to our understanding of this disorder. Changes in systolic function and decreased arterial filling can initiate a cascade of effects that are adaptive in the short-term but maladaptive when elevated chronically, including stimulation of the sympathetic nervous system and the renin-angiotensin-aldosterone axis. Activation of these neurohormonal axes leads to

vasoconstriction, sodium and water retention, increase and redistribution from other vascular beds, increases in diastolic filling pressures, and clinical symptoms. In patients with underlying ischemic heart disease, initial defects in systolic function may initiate a vicious circle of decreasing coronary perfusion, increased myocardial wall stress, and progressively worsening cardiac performance. Increased LV filling pressures and changes in LV geometry can worsen functional mitral regurgitation, further decreasing cardiac output.

Although decreases in systolic function can clearly play a role in the pathophysiology of AHF, epidemiology data summarized earlier show that approximately half of patients with AHF have relatively preserved systolic function. Of importance, abnormalities in diastolic function are present in patients with both preserved and impaired ejection fraction. The impairment of the diastolic phase may be related to passive stiffness or abnormal active relaxation of the left ventricle, or both. Hypertension, tachycardia, and myocardial ischemia (even in the absence of coronary artery disease) can further impair diastolic filling. All of these mechanisms contribute to higher LV end-diastolic pressures, which are reflected back to the pulmonary capillary circulation. Diastolic dysfunction alone may be insufficient to lead to AHF, but it serves as the substrate on which other precipitating factors (such as atrial fibrillation, coronary artery disease, or hypertension) lead to decompensation. One underappreciated aspect of myocardial function in AHF relates to the interdependence of the left and right ventricles. Because of the constraints of the pericardial space, distention of either ventricle secondary to increased filling pressures can result in direct impingement of diastolic filling of the other ventricle. This mechanism may be particularly operative in clinical scenarios leading to abrupt failure of the right ventricle (such as pulmonary embolism or right ventricular [RV] infarction), resulting in diminished filling of the left ventricle and arterial hypotension.

The availability of sensitive assays for circulating cardiac troponins has led to substantial evolution of our understanding of the role of myocardial injury in the pathophysiology of heart failure. Data from both registries and clinical trial populations indicate that circulating cardiac troponins are elevated in a large proportion of patients with AHF, even in the absence of clinically overt myocardial ischemia.^{18,19} In a representative analysis of the ASCEND-HF study, 50% of patients with AHF had troponin levels about the 99th percentile upper reference limit (the diagnostic cut point for myocardial infarction) at baseline and 30% had persistent elevation of troponin at 30 days²⁰ (Fig. 24-3). In a smaller study, more than 20% of patients admitted with AHF and with negative troponins at baseline converted to detectable levels by day 7.²¹ Most studies have indicated that troponin

FIGURE 24-3 Incidence of detectable (above the lower limit of detection) and elevated (above the 99th percentile upper reference limit [URL]) troponin I in the ASCEND-HF study and median cardiac troponin I (cTnI) values in patients with AHF of ischemic versus nonischemic etiology. (From Felker GM, Hasselblad V, Tang WH, et al: Troponin I in acute decompensated heart failure: Insights from the ASCEND-HF study. *Eur J Heart Fail* 14:1257, 2012.)

elevations are associated with increased risk of both in-hospital and postdischarge events.

The precise mechanisms mediating myocardial injury in AHF are poorly defined, but increased myocardial wall stress, decreased coronary perfusion pressure, increased myocardial oxygen demand, endothelial dysfunction, activation of the neurohormonal and inflammatory axes, platelet activation, and altered calcium handling all may contribute to myocyte injury even in the absence of epicardial coronary artery disease.¹⁸ Specific therapeutic interventions that may increase myocardial oxygen demand (such as positive inotropic agents) or decrease coronary artery perfusion pressure (such as some vasodilators) may exacerbate myocardial injury and further contribute to the cycle of decompensation. Whether avoidance of myocardial injury is a specific target for therapy in AHF remains a subject of active investigation.

Renal Mechanisms (see also Chapter 88)

The kidney plays two fundamental roles relative to the pathophysiology of heart failure: It modulates loading conditions of the heart by controlling intravascular volume and is responsible for neurohormonal outputs (i.e., the RAAS system). Abnormalities of renal function are extremely common in patients with AHF and may be underestimated by creatinine alone—64% of patients in the ADHERE registry had a glomerular filtration rate below 60 mL/min/1.73 m².²² Baseline measures of renal function also are well-established risk factors for poor outcomes in AHF (see [Risk Stratification](#) section later on). Additionally, worsening renal function during AHF therapy in the setting of persistent congestion—often termed the “cardiorenal syndrome”—has been associated with poor outcomes in a variety of observational studies.²³ Multiple studies have investigated the pathophysiology and risk factors for this phenomenon, which is related to an intricate interplay of patient characteristics (age), comorbid disease (baseline renal function as assessed by glomerular filtration rate [GFR], diabetes mellitus, hypertension), neurohormonal activation (especially of RAAS and SNS), and hemodynamic factors (central venous congestion, and less frequently arterial underfilling with renal hypoperfusion), as well as other factors such as activation of inflammatory cascades and oxidative stress²⁴ ([Fig. 24-4](#)). Although often assumed to be related to low cardiac output and renal blood flow, careful hemodynamic studies have confirmed that the strongest predictor of worsening renal function in heart failure patients relates to elevated central venous pressure, which is reflected back to the renal veins and leads directly to changes in glomerular filtration rate.²⁵ Specific therapies for AHF such as diuretics may exacerbate renal dysfunction through increasing neurohormonal activation and

vasoconstriction, although in many cases effective diuresis improves renal function by decreasing central venous pressure. It may be important to distinguish between changes in renal function (a potentially transient phenomenon often related to local or systemic hemodynamic factors) and frank renal injury. Transient changes in renal function often occur during AHF therapy, but these frequently are temporary and do not appear to be associated with adverse outcomes, especially in the presence of effective decongestion.^{26,27} Newer biomarkers that may distinguish changes in renal function (as reflected by serum creatinine or cystatin C) from acute kidney injury (as reflected by markers such as urinary neutrophil gelatinase-associated lipocalin [NGAL]) may allow better differentiation of worsening renal function during AHF hospitalization.²⁸ A detailed classification system for understanding the interplay between cardiac performance and renal function has been proposed and provides a framework for understanding the complex pathophysiology underlying the cardiorenal syndrome.^{24,29} Clinical aspects of the diagnosis and management of the cardiorenal syndrome in AHF are covered in more detail later on.

Vascular Mechanisms

Although abnormalities in cardiac function traditionally have held the central position in the pathogenesis of AHF, there is increasing appreciation for the importance of the vasculature not only as an underlying cause of cardiac dysfunction (i.e., atherosclerosis, hypertension) but also as a central component of the pathogenesis of AHF. Abnormalities of endothelial function related to nitric oxide-dependent regulation of vascular tone are well described in heart failure.³⁰ Arterial stiffness, which is related to but distinct from increased blood pressure, increases cardiac loading conditions and is associated with incident heart failure and worse outcomes. Peripheral vasoconstriction in the setting of AHF redistributes blood centrally, increasing pulmonary venous congestion and edema. As noted previously, elevated central venous pressure reduces renal function, resulting in greater fluid retention that further elevates venous pressures. Peripheral arterial vasoconstriction increases afterload, LV filling pressures, and postcapillary pulmonary venous pressures, resulting in worsening of pulmonary edema and dyspnea. This increased afterload causes greater ventricular wall stress and increased myocardial ischemia and cardiac arrhythmias. Abnormal vascular compliance also predisposes affected patients to marked blood pressure lability with relatively minor changes in intravascular volume, causing precipitous increases in afterload and ultimately in LV filling pressures, resulting in pulmonary congestion. The effects of this vascular abnormality are amplified by LV diastolic dysfunction.

The clinical observation that vasodilator treatment can ameliorate dyspnea in many acutely hypertensive patients without significant diuresis has led to the concept that afterload-contraction mismatch can lead to increased diastolic filling pressures in the setting of minimal total body volume changes. Similarly, the recognition of the large capacitance of the venous system (in particular, the splanchnic circulation) has led to increased interest in volume shifts from the “venous reservoir” into the effective circulatory volume as a potentially important and unrecognized mechanism in AHF.^{31,32} These shifts can be mediated by SNS activation, and this mechanism has been proposed as a potential explanation between the apparent disconnect between changes in filling pressures and changes in body weight during chronic hemodynamic monitoring.

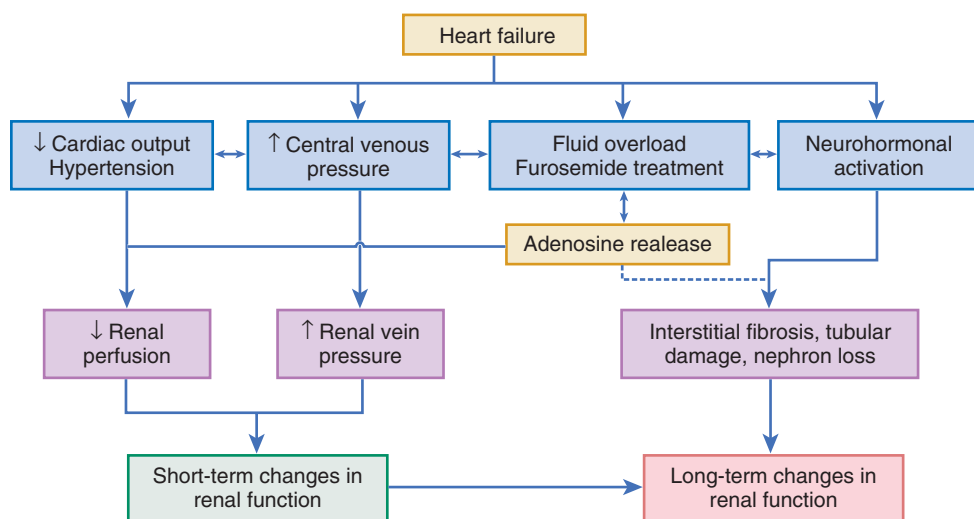

FIGURE 24-4 A schematic of interactions among renal perfusion, central venous pressure, and acute and chronic kidney injury. (From Metra M, Cotter G, Gheorghiade M, et al: *The role of the kidney in heart failure*. *Eur Heart J* 33:2135, 2012.)

Neurohormonal and Inflammatory Mechanisms (see also Chapter 22)

Although elevations of circulating neurohormones are well documented in patients with AHF, the precise role of neurohormonal activation in the pathophysiology of AHF remains to be fully delineated. Increased plasma concentrations of norepinephrine, plasma renin activity, aldosterone, and endothelin-1 have been reported in patients with AHF; all of these axes are associated with vasoconstriction and volume retention, which could contribute to myocardial ischemia and congestion, thereby exacerbating cardiac decompensation. Inflammatory activation and oxidative stress may also play a role. Proinflammatory cytokines such as tumor necrosis factor- α and interleukin-6 are elevated in patients with AHF and have direct negative inotropic effects on the myocardium as well as increasing capillary permeability and inducing endothelial dysfunction.^{33,34} In addition to direct effects, this activation stimulates the release of other factors, such as the potent procoagulant tissue factor and endothelin-1, which can lead to further myocardial suppression, disruption of the pulmonary alveolar-capillary barrier, and increased platelet aggregation and coagulation (potentially worsening ischemia).

EVALUATION OF THE PATIENT WITH ACUTE HEART FAILURE

The initial evaluation of the patient with AHF focuses on the following critical aspects: (1) establishing a definitive diagnosis of AHF as rapidly and efficiently as possible; (2) emergent treatment for potentially life-threatening conditions (e.g., shock, respiratory failure); (3) identifying and addressing any relevant clinical triggers; (4) risk stratification for triage of the patient to an appropriate level of care (e.g., intensive care unit, telemetry unit, observation unit); and (5) defining the clinical profile of the patient (based on blood pressure, volume status, and renal function) to allow rapid implementation of the most appropriate therapy.

Classification

The inherent heterogeneity of AHF makes the development of a comprehensive classification scheme difficult, and no single classification system has garnered universal acceptance. The potential value of clinical classification is to provide a framework for identifying important clinical subgroups within the spectrum of AHF that might have an impact on choice of therapy and clinical course—analogueous to the distinction among ST-segment elevation myocardial infarction, non-ST-segment elevation myocardial infarction, and unstable angina in patients with acute ischemic heart disease.

One potentially useful method of classification is based on the presence or absence of a previous history of heart failure. New-onset or de novo heart failure accounts for approximately 20% of hospitalizations for AHF.¹⁰ Patients may have no previous history of cardiovascular disease or risk factors (e.g., acute myocarditis), but more commonly, they have a background of risk factors for heart failure (stage A heart failure according to the American College of Cardiology/American Heart Association [ACC/AHA] guidelines) or preexisting structural heart disease (stage B heart failure according to the ACC/AHA guidelines) (see also Chapters 23 and 25). In many of these patients with de novo heart failure, AHF develops in the setting of acute coronary syndrome. The vast majority of patients with AHF, however, have a history of preexisting chronic heart failure. These patients usually have a less dramatic clinical presentation, because the chronic nature of the disorder has allowed for recruitment of compensatory mechanisms and remodeling (e.g., increased pulmonary lymphatic capacity). Additionally, these patients typically are already being treated with neurohormonal antagonists (beta blockers and angiotensin-converting enzyme [ACE] inhibitors) and loop diuretics, such that neurohormonal activation may be less profound but diuretic resistance may be more common.

A variety of additional classification frameworks have attempted to classify patients with AHF in a way that might have implications for clinical care. The most detailed classification is outlined in the ESC guidelines, which subdivides AHF into multiple different clinical scenarios based on baseline characteristics and response to therapy.² Inasmuch as some of the proposed categories in the ESC guidelines may have significant overlap, we suggest a simplified classification scheme that defines three general groups of patients with AHF (Table 24-2):

1. *Decompensated heart failure.* This group is composed of patients with worsening signs and symptoms of congestion on a background of chronic heart failure. The time course of this progression may be acute, subacute, or indolent, with gradually worsening symptoms over days to weeks. They may have either preserved or reduced ejection fraction, but cardiac output generally is preserved and blood pressure is within the normal range. Overall, this group represents the largest proportion of patients hospitalized for AHF.
2. *Acute hypertensive heart failure.* Hypertension is increasingly recognized as a common feature of the AHF presentation, with 50% of patients presenting with systolic blood pressure (SBP) higher than 140 mm Hg and 25% with SBP higher than 160 mm Hg.³⁵ In this group, hypertension may be triggered by a high sympathetic tone related to dyspnea and accompanying anxiety (reactive hypertension) or acute hypertension with accompanying changes in afterload may be a trigger for decompensation. Both of these mechanisms may be operative in a given patient, and

TABLE 24-2 Simplified Classification and Common Clinical Characteristics of Patients with Acute Heart Failure

CLINICAL CLASSIFICATION	SYMPTOM ONSET	TRIGGERS	SIGNS AND SYMPTOMS	CLINICAL ASSESSMENT	COURSE
Decompensated heart failure	Usually gradual	Noncompliance, ischemia, infections	Peripheral edema, orthopnea, dyspnea on exertion	SBP: variable CXR: often clear despite elevated filling pressures	Variable; high rehospitalization rate
Acute hypertensive heart failure	Usually sudden	Hypertension, atrial arrhythmias, ACS	Dyspnea (often severe), tachypnea, tachycardia, rales common	SBP: high (>180/100 mm Hg) CXR: evidence of pulmonary edema Hypoxemia common	High acuity but often responds quickly to therapy with vasodilators, noninvasive ventilation; low postdischarge mortality
Cardiogenic shock	Variable	Progression of advanced HF or major myocardial insult (e.g., large-infarct AMI, acute myocarditis)	End-organ hypoperfusion; oliguria, confusion, cool extremities	SBP: Low or low-normal LV function usually severely depressed RV dysfunction common Laboratory evidence of end-organ dysfunction (renal, hepatic)	High inpatient mortality; poor prognosis except with readily reversible cause or mechanical support/transplantation

AMI = acute myocardial infarction; CXR = chest x-ray [film/examination]; HF = heart failure.

cause-and-effect relationships may be difficult to discern with precision. Epidemiologically, patients in whom acute hypertensive heart failure are more likely to have preserved systolic function, more likely to be women, and more likely to experience sudden onset of symptoms. Frank pulmonary edema with evident rales and florid congestion on the chest radiograph is much more common in this group of patients than in those with more gradual onset of symptoms, probably related to differences in LV compliance, acuity of pressure changes, and pulmonary lymphatic capacity. Although often strikingly ill at the time of initial presentation with hypoxemia and the possible need for noninvasive ventilation or even intubation, these patients tend to respond well to therapy and have low in-hospital mortality.

3. **Cardiogenic shock.** This group presents with signs and symptoms of organ hypoperfusion despite adequate preload. SBP often (although not always) is decreased, and evidence of frank or impending end-organ dysfunction (renal, hepatic, central nervous system) is common. This type of AHF is relatively uncommon (4% of AHF presentations in EHFS II) in broad community registries but is more common in tertiary care settings.

Although this classification system does not fully capture some less common clinical scenarios (e.g., isolated right-sided heart failure or high-output heart failure), it usefully encompasses the vast majority of patients with AHF likely to be seen in routine clinical practice. The management of several specific clinical scenarios in AHF is discussed in more detail later on.

Symptoms

The most common reasons for patients to seek medical care for AHF are symptoms related to congestion. A list of the most common presenting symptoms is provided in [Table 24-3](#). Dyspnea is the most common symptom and is present in 90% of patients presenting with AHF. The duration and time course of symptom onset can vary markedly, from very acute onset over minutes to slow worsening of chronic symptoms until the patient seeks medical attention. The sensation of dyspnea is a complex phenomenon that is influenced by multiple physiologic, psychological, and social factors and can vary dramatically between patients.³⁶ Dyspnea typically is present at rest or with minimal exertion by the time the patient presents with AHF. Patients also may present with signs and symptoms related to systemic venous congestion, including peripheral edema, weight gain, early satiety, and increasing abdominal girth. Of importance, atypical symptoms can predominate, especially in elderly patients, in whom fatigue, depression, altered mental status, or sleep disruptions may be the primary complaint.

Physical Examination

Despite advances in diagnostics technology and imaging, heart failure remains a clinical diagnosis, and the physical examination continues to play a fundamental role in its detection. Aspects of the physical examination of particular importance in AHF are covered here; for a more general discussion of the history and physical examination, [see Chapters 11 and 23](#). A useful framework for bedside evaluation of patients with AHF is that developed by Stevenson and colleagues (see Fig. 23-2), which focuses on the adequacy of perfusion (“cold” versus “warm”) and presence or absence of congestion at rest (“wet” versus “dry”).

Measuring the blood pressure is a critical part in the evaluation of patients with AHF; hypotension is one of the strongest predictors of poor outcomes and helps to define the clinical profile of the patient and appropriate therapeutic interventions. SBP typically is normal or elevated in patients with AHF, with almost 50% presenting with SBP greater than 140 mm Hg. The combination of underlying hypertension and the marked increase in sympathetic stimulation that accompanies AHF can result in elevations of SBP consistent with hypertensive urgencies or emergencies (12% of patients had an SBP over 180 mm Hg on admission). Very low SBP is uncommon, with only 2% of patients in ADHERE presenting with values below

TABLE 24-3 Common Presenting Symptoms and Signs of Decompensated Heart Failure

SYMPTOMS	SIGNS
Predominantly Related to Volume Overload	
Dyspnea (exertional, paroxysmal nocturnal dyspnea, orthopnea, or at rest); cough; wheezing	Rales, pleural effusion
Foot and leg discomfort	Peripheral edema (legs, sacral)
Abdominal discomfort/bloating; early satiety or anorexia	Ascites/increased abdominal girth; right upper quadrant pain or discomfort; hepatomegaly/splenomegaly; scleral icterus
	Increased weight
	Elevated jugular venous pressure, abdominojugular reflux
	Increasing S ₃ , accentuated P ₂ heart sounds
Predominantly Related to Hypoperfusion	
Fatigue	Cool extremities
Altered mental status, daytime drowsiness, confusion, or difficulty concentrating	Pallor, dusky skin discoloration, hypotension
Dizziness, presyncope, or syncope	Pulse pressure (narrow)/proportional pulse pressure (low)
	Pulsus alternans
Other Signs and Symptoms of AHF	
Depression	Orthostatic hypotension (hypovolemia)
Sleep disturbances	S ₄
Palpitations	Systolic and diastolic cardiac murmurs

90 mm Hg. Pulse pressure (the difference between systolic and diastolic blood pressures) is a useful measure that is an indirect marker of cardiac output. A low pulse pressure correlates with low cardiac output and confers an increased risk in patients admitted with AHF. A high pulse pressure may alert the physician to a high-output state, including the possibility of unrecognized thyrotoxicosis, aortic regurgitation, or anemia.

The jugular venous pressure (JVP) is literally a barometer of systemic venous hypertension and is the single most useful physical examination finding in the assessment of patients with AHF. The accurate assessment of the JVP is highly dependent on examiner skill. The JVP reflects the right atrial pressure, which typically (although not always) is an indirect measure of LV filling pressures. Important situations where JVP may not reflect LV filling pressures include isolated RV failure (e.g., from pulmonary hypertension or RV infarct). Significant tricuspid regurgitation can complicate assessment of the JVP because the large “c-v wave” of tricuspid regurgitation can lead to overestimation of the JVP and hence left-sided filling pressures.

Visual inspection and palpation of the precordium, followed by careful auscultation, provide important clues to the presence of cardiac dysfunction. S₃ gallops or third heart sounds are detected in approximately 11% to 34% of patients admitted with AHF. Murmurs of mitral or aortic regurgitation or aortic stenosis can provide important clues to the etiology of AHF.

Rales or inspiratory crackles are the most common physical examination finding and have been noted in 66% to 87% of patients admitted for AHF. However, rales are often not heard in patients with a background of chronic heart failure and pulmonary venous hypertension, because of increased lymphatic drainage, reinforcing the important clinical pearl that the absence of rales does not necessarily imply normal LV filling pressures. Cool extremities with palpable peripheral pulses suggest decreased peripheral perfusion consistent

with a marginal cardiac index, marked vasoconstriction or both. Of note, the temperature should be assessed at the lower leg as opposed to the foot, and this assessment is relative to the temperature of the examiner hands.

Peripheral edema is present in up to 65% of patients hospitalized with AHF and is less common in patients presenting with predominantly low-output heart failure or cardiogenic shock. As with rales, the presence of edema has a reasonable positive predictive value for acutely decompensated heart failure but a low sensitivity, so its absence does not exclude that diagnosis. Edema resulting from AHF usually is dependent, symmetric, and pitting. It is estimated that a minimum of 4 liters of extracellular fluid is accumulated to produce clinically detectable edema. Hepatomegaly and splenomegaly can occur acutely in patients with AHF as a consequence of increased central venous pressure and in such cases often result in significant tenderness, but these conditions more often are the result of chronic systemic venous hypertension, when minimal tenderness, if any, is present. Severe tricuspid regurgitation can result in a pulsatile liver on examination and in congestive cirrhosis. Ascites occurs in response to elevated central venous pressures by retarding emptying of the peritoneal veins and the hepatic veins. Of note, visceral congestion may occur independently of ascites or palpable organomegaly.

Other Diagnostic Testing

Biomarkers

The natriuretic peptides are a family of important counterregulatory hormones in heart failure with vasodilatory and other effects (see Chapter 23). In the context of AHF, both brain natriuretic peptide (BNP) and N-terminal pro-brain natriuretic peptide (NT-proBNP) have been shown to play an important role in the differential diagnosis in patients presenting in the emergency department with dyspnea (see Table 23-6).³⁷ In the Breathing Not Properly study, a BNP threshold of 100 pg/mL maximized sensitivity and specificity to differentiate dyspnea that was ultimately confirmed to be due to AHF (based on a review of clinical data by a blinded panel of cardiologists) from dyspnea from other causes. Of importance, the negative predictive value of a BNP level less than 100 pg/mL was particularly high (89%), whereas the positive predictive value of this decision threshold was more modest (79%). Subsequent studies using NT-proBNP, such as the PRIDE study, have shown that NT-proBNP has similar diagnostic value, although the appropriate cut points are higher overall and vary with age.³⁸ In current clinical guidelines, natriuretic peptide testing in the diagnosis of acute dyspnea is currently the only class I indication for a biomarker test in heart failure.³⁹ As with all biomarker testing, false positives (e.g., caused by myocardial infarction or pulmonary embolism) and false negatives (primarily caused by obesity, which results in lower NP levels for a given degree of heart failure) may occur. Although natriuretic peptide levels tend to be lower in patients with HFpEF than those with reduced systolic function, natriuretic peptide testing cannot reliably distinguish HFpEF from systolic heart failure in an individual patient.

Other Laboratory Testing

Assessment of renal function is a critical component in the management of patients with AHF. An estimated glomerular filtration rate should be calculated because serum creatinine may underestimate the degree of renal dysfunction, especially in elderly patients. Blood urea nitrogen (BUN) is more directly related to the severity of AHF than creatinine and typically is elevated on admission in a large proportion of patients with AHF. In addition to reflecting intrinsic renal function, the BUN level is roughly proportional to neurohormonal activation in AHF. A wide variety of other biomarkers have been evaluated in patients with AHF, but none are currently recommended for routine use in this population.⁴⁰

Chest Radiography, Electrocardiogram, and Echocardiogram

Chest radiography commonly is performed at the time of presentation in patients with dyspnea and is a fundamental test in the

evaluation for suspected AHF. In the ADHERE registry, 90% of patients underwent chest radiography during hospitalization, and evidence of congestion was found in more than 80% of these patients. In patients with a background of chronic heart failure and/or slow onset of symptoms, evidence of congestion on the chest radiograph may be subtle, and frank pulmonary edema often is absent despite substantially elevated filling pressures.

The electrocardiogram (ECG) is another standard diagnostic test that is appropriate in all patients presenting with AHF (see Chapter 12). ECG abnormalities are extremely common in patients with AHF. Careful attention for ECG changes suggestive of ischemia is of importance, because troponin elevation is common in AHF regardless of cause and thus may not be a reliable marker of acute coronary syndromes. Arrhythmias also are a common trigger for AHF, and atrial fibrillation is present in 20% to 30% of patients who present with AHF.

Use of echocardiography (see Chapter 14) is very high in patients with AHF—more than 80% of patients in EHFS II had an echocardiogram performed during the index hospitalization.¹⁰ Although the appropriateness of routine echocardiography in all patients with AHF is controversial, an echocardiogram is perhaps the single most useful test in investigation of the cause of AHF. Echocardiography can assess global systolic and diastolic function, regional wall motion abnormalities, valvular function, hemodynamics including estimates of filling pressures and cardiac output, and pericardial disease. The tissue Doppler ratio of peak early diastolic transmitral blood flow velocity (E) to the peak early diastolic mitral annular tissue velocity (Ea) (E/Ea ratio) has been shown to be additive to BNP measures in diagnosing patients with AHF presenting with dyspnea. An E/Ea ratio higher than 15 predicts a pulmonary capillary wedge pressure (PCWP) greater than 15 mm Hg and has been demonstrated to be accurate in the emergency department and intensive care settings. These and other noninvasive measures will require further validation before they can be adopted broadly, and the role of routine echocardiography in all patients hospitalized with AHF remains uncertain.

Clinical Triggers

Whereas the preceding section focused on intrinsic mechanisms involved in the pathophysiology of AHF, a variety of specific identifiable clinical triggers may be identified as well. Although some of these triggers have long been recognized, only the recent advent of large observational registries has provided more definitive data on their relative contribution in the broader heart failure population. In the OPTIMIZE-HF registry, 61% of enrolled subjects had an identifiable clinical precipitant, with pulmonary processes (15%), myocardial ischemia (15%), and arrhythmias (14%) being the most common⁴¹ (Fig. 24-5). More than one precipitant was identified in a substantial minority of the study population. Of the identified triggers, worsening renal function was responsible for the highest in-hospital mortality rate (8%), whereas nonadherence to diet or medication or uncontrolled hypertension was associated with a much better prognosis (<2% in-hospital mortality for each). In general, the specific clinical triggers identified have varied significantly in accordance with the methods of ascertainment and the population studied.

Risk Stratification

Risk stratification can serve as important clinical tools by helping to identify those patients at both ends of the spectrum of risk; patients who are at very high risk may be observed more closely or treated more intensively, whereas patients at low risk may avoid hospitalization altogether or need less rigorous follow-up and monitoring. A variety of predictive models have been developed in AHF, which generally can be divided into two groups: those focused on in-hospital mortality, and those focused on postdischarge events (death or rehospitalization). Selected key predictors of outcome in AHF are shown in Figure 24-6.

Predictive Models of In-Hospital Mortality

Data from the ADHERE registry have been used to develop a classification and regression tree (CART) analysis to identify the best

FIGURE 24-5 Identified triggers for acute heart failure hospitalization in the OPTIMIZE-HF Registry. HTN = hypertension. (From Fonarow GC, Abraham WT, Albert NM, et al: Factors identified as precipitating hospital admissions for heart failure and clinical outcomes: Findings from OPTIMIZE-HF. Arch Intern Med 168:847, 2008.)

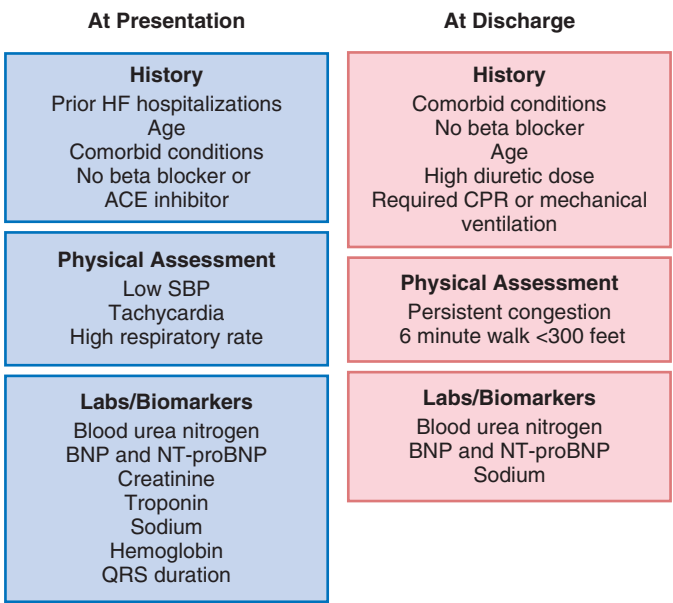

FIGURE 24-6 Selected prognostic indicators in acute heart failure at the time of initial presentation and at the time of hospital discharge. CPR = cardiopulmonary resuscitation; HF = heart failure.

predictors of in-hospital mortality and to develop a risk stratification model.⁴² Of the 39 variables evaluated, the CART method identified elevated BUN, lower SBP, and higher serum creatinine at the time of admission to be the best predictors of in-hospital mortality. These three variables allowed for discrimination of groups with very low (2%) or extremely high (22%) in-hospital mortality.

Predictive Models of Postdischarge Events

As noted, both the risk of death and likelihood of rehospitalization are substantial in the first 60 to 90 days after discharge in patients with AHF. Some variables may predict mortality but not

rehospitalization, and vice versa. In general, models for prediction of mortality have performed better than models focused on the composite of death or rehospitalization, potentially because rehospitalization risk is influenced by a variety of social factors not easily captured in multivariable models. As discussed further on, in keeping with the current major focus on preventing rehospitalization in AHF, models for predicting rehospitalization have been of substantial interest. A systematic review of models identified a number of models focused on predicting rehospitalization after AHF event but failed to identify a consistent pattern of predictors across studies.⁴³ However, a few readily available markers have generally been associated with prognosis across multiple studies and are summarized next in more detail.

Blood Pressure. SBP has been found to be an important predictor of outcomes in a variety of studies, with higher blood pressure consistently associated with lower risk. In a detailed analysis of SBP in patients from the OPTIMIZE-HF study, a relatively monotonic relationship was found between blood pressure and mortality across the spectrum of blood pressure, with no evidence of increased risk even at very high levels of blood pressure (>180 mm Hg).³⁵

Blood Urea Nitrogen. Renal function (estimated by BUN, serum creatinine, and glomerular filtration rate) is an important predictor of prognosis in patients with AHF.⁴² Of note, BUN has consistently been shown to be a stronger predictor of outcome than creatinine: When compared head to head, BUN appears to integrate a variety of important prognostic aspects, including intrinsic renal function and neurohormonal activation (as a result of impaired urea clearance).^{44,45}

Brain Natriuretic Peptide and N-terminal Pro-Brain Natriuretic Peptide. BNP and NT-proBNP have been demonstrated to be powerful predictors of risk in heart failure. In the setting of AHF, natriuretic peptide levels at initial presentation are important predictors of both short-term and long-term outcomes. In the PRIDE study of patients presenting to the emergency department with unexplained dyspnea, a single NT-proBNP value at initial presentation was an independent predictor of death out to 1 year.⁴⁶ In the ADHERE registry, admission BNP level was a significant predictor of in-hospital mortality regardless of ejection fraction. Data from the OPTIMIZE registry comparing admission BNP, discharge BNP, and change in BNP over the course of hospitalization identified discharge BNP as having the greatest power for predicting postdischarge events.⁴⁷

MANAGEMENT OF THE PATIENT WITH ACUTE HEART FAILURE

Phases of Management

A central aspect of AHF is the need for urgent care beyond that typically given in the outpatient setting. The management of patients with AHF may be considered in the context of four phases of treatment with distinct goals. To achieve these goals, a seamless integration of the various phases of management with a high level of coordination between the in-hospital and postdischarge caregivers is necessary. Different treatment strategies and a detailed description of various therapies are presented later.

Phase I: Urgent/Emergent Care

The initial goals in the management of a patient presenting with AHF are to expeditiously establish the diagnosis (as discussed earlier), treat life-threatening abnormalities, initiate therapies to rapidly provide symptom relief, and identify the cause and precipitating triggers for the episode of AHF.

Initial therapies may follow the algorithm in **Figure 24-7**. Insofar as dyspnea is the most common complaint in patients with AHF, the initial management of uncomplicated AHF usually targets this symptom.⁴⁸ In patients with severe hypoxemia (oxygen saturation [SaO_2] <90%), oxygen administration is recommended. Although oxygen saturation on presentation is inversely related to short-term mortality,⁴⁹ inhaled oxygen ($\text{FiO}_2 \geq 0.4$) may cause detrimental hemodynamic effects (such as hyperoxia-induced vasoconstriction) in patients with systolic dysfunction,⁵⁰ so it is not routinely recommended for patients without hypoxemia. In patients with obstructive pulmonary disease, high concentrations of inhaled oxygen should not be used, to avoid the risk of respiratory depression and worsening hypercarbia. Early clinical studies and meta-analyses suggest that in patients with cardiogenic pulmonary edema, treatment with continuous positive airway pressure (CPAP) or noninvasive intermittent positive-pressure ventilation (NIPPV) helps alleviate symptoms, optimizes physiologic variables, and reduces the need for invasive ventilation and mortality.⁵¹ The Three Interventions in Cardiogenic Pulmonary Oedema (3CPO) trial enrolled 1069 patients with pulmonary edema who were randomly assigned to receive standard oxygen therapy, CPAP, or NIPPV.⁵² Noninvasive ventilation (NIV) with CPAP or NIPPV was associated with greater improvement in patient-reported dyspnea, heart rate, acidosis, and hypercapnea after 1 hour of therapy, although it was not associated with a 7-day mortality benefit or with decreased need for intubation when compared with standard oxygen therapy. CPAP typically is initiated with a positive end-expiratory pressure (PEEP) of 5 to 7.5 cm H_2O , titrated to 10 cm H_2O as needed for dyspnea relief and improvement in O_2 saturation. Contraindications to the use of NIV include immediate need for endotracheal intubation (inability to protect the airway, life-threatening hypoxia) and lack of patient cooperation (altered sensorium, unconsciousness, anxiety, inability to tolerate mask). Caution is indicated with use of these modalities in patients with cardiogenic shock, RV failure, and severe obstructive airway disease. Potential side effects and complications include anxiety, claustrophobia, dry mucous membranes, worsening RV failure, hypercapnea, pneumothorax, and aspiration. Mechanical ventilation with endotracheal intubation is required in approximately 4% to 5% of all patients.^{10,53} Morphine may be useful in patients with severe anxiety or distress but should be used cautiously or avoided, especially in the presence of hypotension, bradycardia, advanced atrioventricular block, or CO_2 retention. Morphine use has been associated with increased likelihood of mechanical ventilation, requirement for intensive care unit (ICU) admission, prolonged hospital stay, and death in some retrospective analyses.

Intravenous loop diuretics are the most frequently administered pharmacologic agents for AHF; more than 75% of patients in the emergency department receive intravenous diuretics, with a mean door to first intravenous administration time of 2.2 hours reported in ADHERE.⁵³ Although some patients with volume redistribution rather than hypervolemia may derive benefit from vasodilators alone,

symptomatic patients with objective evidence of congestion consistent with pulmonary or systemic venous hypertension or edema should receive urgent diuretic therapy for rapid relief of dyspnea.⁵⁴ Initial therapy typically consists of a bolus injection with a dose between 1 and 2.5 times the patient's oral loop diuretic dose for patients on chronic diuretic therapy (see later section, **Diuretics**). In the absence of hypotension, vasodilators play an important role in the initial therapy of patients with pulmonary edema and poor oxygenation. A treatment strategy of early initiation of intravenous nitrate therapy in patients with severe cardiogenic pulmonary edema has been shown to reduce the need for mechanical ventilation and the frequency of myocardial infarction.⁵⁵

After the emergent care of the patient, evaluation for triage is performed, and a critical decision point concerns the decision of whether to admit the patient to the hospital. Although low-risk patients may potentially be discharged with careful follow-up monitoring, the vast majority of patients who present to the emergency department with AHF are hospitalized.⁵⁶ Although less than 5% of patients with heart failure are initially treated in an emergency department observation unit, these specialized care centers may be effective in decreasing hospitalizations, ICU and critical care unit (CCU) admissions, and related health care costs while maintaining the quality of patient care.⁵⁷ In general, hospitalization is recommended for patients with evidence of severe decompensated heart failure, including hypotension, worsening renal function or altered mentation; dyspnea at rest associated with either tachypnea or, less commonly, significant hypoxemia (oxygen saturation <90%); hemodynamically significant arrhythmia (most commonly atrial fibrillation either with rapid ventricular response or new onset); and acute coronary syndromes. Hospitalization should be considered in patients with worsened congestion, even in the absence of dyspnea and often reflected by significant weight gain (≥ 5 kg), other signs or symptoms of pulmonary or systemic congestion, newly diagnosed heart failure, complications of heart failure therapy (such as electrolyte disturbances, frequent implantable cardioverter-defibrillator [ICD] firings) or other associated comorbid conditions.⁵⁸

Specific Clinical Presentations

Atrial Fibrillation with Rapid Ventricular Response. Atrial fibrillation (see **Chapter 38**) with rapid ventricular response is the most common tachyarrhythmia requiring treatment in patients with AHF. It may be difficult to determine with certainty whether the atrial fibrillation was a trigger for AHF or whether progressive heart failure decompensation led to atrial fibrillation. Although the ventricular response frequently decreases in parallel with the relief of dyspnea, and consequent decreased sympathetic drive, additional therapy may be required. Immediate cardioversion generally is not indicated except in the unstable patient, as cardioversion while the patient remains significantly decompensated is associated with a high rate of recurrent atrial fibrillation.¹² In patients with systolic dysfunction, intravenous digoxin (in the absence of an accessory pathway), cautious use of beta-blocker therapy, or amiodarone may be used. Diltiazem and other agents that suppress ventricular function should be avoided in patients with significant systolic dysfunction, but may be effective in patients with preserved function.

Right Ventricular Heart Failure. The most common cause of RV heart failure in AHF is left-sided failure. Isolated RV heart failure is relatively rare and is generally due to acute RV infarction, acute pulmonary embolism, or severe pulmonary hypertension. Isolated RV heart failure caused by an acute RV infarction is best treated with early reperfusion, whereas hemodynamically significant pulmonary embolism may be treated with thrombolytics. Hemodynamic stabilization by optimizing central venous pressures via carefully monitored fluid loading (target central venous pressure [CVP], approximately 10 to 12 mm Hg) and increasing RV systolic function with intravenous inotropic support under invasive hemodynamic guidance may also be necessary.⁵⁹ Selective pulmonary artery vasodilation by inhaled (nitric oxide, prostacyclin analogues) or intravenous (prostacyclin analogues, sildenafil) agents may improve RV function through decreased afterload. If the patient is mechanically ventilated, normoxia and hypocarbia should be goals using moderate tidal volumes (approximately 8 mL/kg) and as low a PEEP as possible (<12 cm H_2O) to maintain moderate plateau pressures.

Acute Coronary Syndromes. Acute coronary syndromes (ACSs) (see **Chapters 51 and 52**) may be the underlying trigger in patients

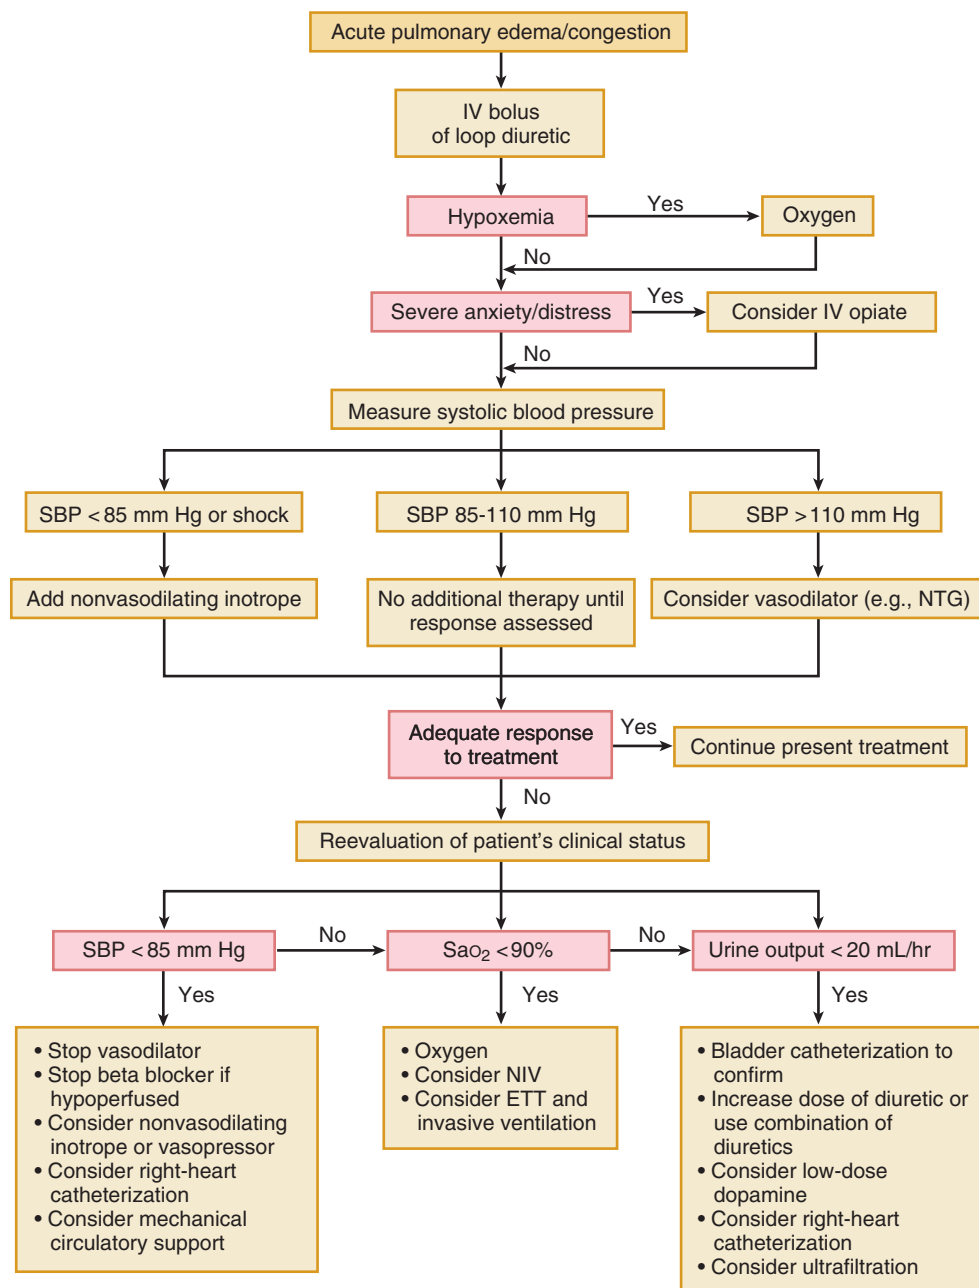

FIGURE 24-7 Algorithm for management of patients admitted with AHF and pulmonary edema/congestion. ETT = endotracheal tube; IV = intravenous; NTG = nitroglycerin. (Modified from McMurray JJ, Adamopoulos S, Anker SD, et al: ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure 2012: The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012 of the European Society of Cardiology. Developed in collaboration with the Heart Failure Association (HFA) of the ESC. *Eur Heart J* 33:1787, 2012.)

presenting with AHF, but as noted earlier, the diagnosis is confounded by the high prevalence of elevated troponins associated with AHF itself. These patients may present with chest discomfort, electrocardiographic changes consistent with ischemia, and elevated serum troponin. Aggressive therapy for acute coronary syndrome (ACS) should be rapidly instituted (see Chapter 52). In the absence of cardiogenic shock, inodilators should be avoided in patients with ACS and those with significant asymptomatic coronary disease, because experimental data have shown that they can cause necrosis of ischemic and/or hibernating myocardium.

Cardiogenic Shock. Cardiogenic shock (see Chapter 52) is characterized by marked hypotension (SBP <80 mm Hg) lasting more than 30 minutes, associated with severe reduction of cardiac index (usually <1.8 L/min/m²) in spite of adequate LV filling pressure (PCWP >18 mm Hg), resulting in organ hypoperfusion. Cardiogenic shock is an unusual presentation of AHF, reported in less than 4% of the patients in EHFS II,¹⁰ most of whom had a myocardial infarction.

Mechanical complications of acute myocardial infarction (AMI) such as mitral regurgitation, cardiac rupture with ventricular septal defect or tamponade, and isolated RV infarct also may be causes in this setting. Intravenous inotropes or even vasoconstrictors may be required in these patients, with mechanical circulatory support, such as with an intra-aortic balloon pump (IABP) or LV assist device (LVAD), for critical refractory cases, as a bridge to heart transplantation or other mechanical intervention. In addition to these therapies, pulmonary artery catheter insertion, echocardiographic evaluation, and urgent cardiac catheterization usually are indicated.

Phase II: Hospital Care

The goals in management of the patient with AHF during the hospitalization phase are to complete the diagnostic and acute therapeutic processes that were initiated at the time of initial presentation, to optimize the patient's hemodynamic profile and volume status and control clinical symptoms, and to initiate or optimize chronic HF therapy. Ideally, these goals would be met in a manner to minimize intensive care and total hospital length of stay. Monitoring of daily weights, fluid intake and output, and vital signs, including orthostatic blood pressure, as well as a daily assessment of symptoms and signs, is crucial. Laboratory monitoring should include daily analysis of electrolytes and renal function. Diagnostic evaluations should include an echocardiogram, if not recently performed, and evaluation for myocardial ischemia, if clinically indicated. Dietary sodium restriction (to 2 g daily) and fluid restriction (to 2 L daily) may be useful to help treat congestion. The increased risk of venous thromboembolism in heart failure is exacerbated by the decreased mobility of hospitalized patients with AHF, and venous thromboembolism prophylaxis is indicated in all patients unless a clear contraindication is recognized.

Most outpatient medications should be continued during hospitalization, although in patients with worsening renal function, ACE inhibitors and mineralocorticoid receptor antagonists often are withheld. Patients admitted on beta blockers had a lower occurrence of ventricular arrhythmias, a shorter length of stay, and reduced 6-month mortality compared with those not receiving them, and in those who were maintained on their therapy, significantly higher outpatient use of beta blockers and a lower rate of rehospitalization and death within 6 months after discharge were documented, even after adjustments for potential confounders.^{60,61} Patients should therefore continue beta blocker therapy during hospitalization for AHF, unless significant hypotension or cardiogenic shock is present. In the absence of contraindications, ACE inhibitors, angiotensin receptor blockers, mineralocorticoid receptor antagonists, and isosorbide dinitrate/hydralazine should be continued during the hospitalization as well. Identification of other untreated targets (e.g.,

revascularization, consideration of cardiac resynchronization therapy in appropriate candidates) should be performed during the hospitalization. The hospitalization phase of AHF management also constitutes a tremendous opportunity to provide education and behavioral therapies to patients. Patients should receive specific and clear education about heart failure, including indications for specific drugs, outpatient monitoring of fluid status through daily weights, self-adjustment of diuretics, exercise programs, and nutritional counseling, as well as possible consultation with physical and occupational therapy. Comorbid conditions should be aggressively addressed because these often complicate heart failure management. The hospitalization also is a possible opportunity to enroll the patient in appropriate heart failure disease management programs.

The Cardiorenal Syndrome in Hospitalized Patients

The *cardiorenal syndrome* (see Chapter 88) represents one of the greatest therapeutic challenges in the field of AHF. Although no consensus definition has emerged to date, one definition of the cardiorenal syndrome is the clinical state in which the volume overload of heart failure is resistant or refractory to treatment because of progressive renal insufficiency. A commonly used practical definition is an increase in serum creatinine above 0.3 mg/dL (or 25% decreases in GFR) despite evidence of persistent clinical or hemodynamic congestion. By this definition, the cardiorenal syndrome occurs in approximately 25% to 35% of the patients admitted with AHF, associated with longer lengths of stay and higher postdischarge mortality rates.²³ This definition of the cardiorenal syndrome emphasizes the importance of persistent congestion, because multiple studies have suggested that changes in renal function during successful decongestion therapy usually are transient and may not be associated with adverse outcomes.^{26,27}

Although the diagnosis of cardiorenal syndrome may be straightforward, the clinical management is a major challenge. Because absolute serum creatinine concentrations can be misleading, estimated GFR (eGFR) should be calculated in patients with AHF. As noted previously, arterial underfilling resulting from overdiuresis or low cardiac output does not appear to be the most frequent primary cause of worsening renal function, although hypotension can be an important factor.⁶² Progressive deterioration of renal function (BUN >80 mg/dL and serum creatinine >3.0 mg/dL) or hyperkalemia may necessitate discontinuation of ACE inhibitors and spironolactone, although use of other vasodilators should be considered, either intravenous (i.e., nitroglycerin or nitroprusside) or oral (isosorbide dinitrate and hydralazine). Increasing doses of diuretics typically are required, although diuretic resistance may be profound. Although ultrafiltration often is considered in this scenario, a recent randomized clinical trial, the CARRESS study, found that a stepped pharmacologic care approach focused on escalation of diuretics; the use of vasodilators was superior to ultrafiltration with regard to preserving renal function and equivalent in terms of decongestion.⁶³ Overall, the appropriate management of patients with cardiorenal syndrome remains a major unmet clinical challenge in AHF.

Phase III: Predischage Planning

The predischage phase focuses on the goals of evaluating readiness for discharge, optimizing chronic oral therapy, minimizing the side effects of treatments, and ultimately preventing early readmission and improving symptoms and survival. Although there may be considerable pressures to rapidly discharge patients (particularly in the United States), careful optimization of medical regimen before discharge may reduce the risk of subsequent readmissions and improve long-term outcomes.⁶⁴ Despite the fact that most patients present with congestion, many patients are discharged without significant weight loss, and a recent analysis of the EVEREST study confirmed that persistent clinical congestion at discharge was associated with a high risk for rehospitalization.⁶⁵ Similarly, elevations of discharge BNP level have been shown to be associated with risk for subsequent rehospitalization.⁶⁶ Evaluation of functional capacity with simple maneuvers such as climbing one flight of stairs or walking down the corridor may be a simple and valuable tool to use before discharge.

TABLE 24-4 Criteria for Discharge after Hospitalization for Acute Heart Failure

Recommended for All Patients with Heart Failure (HF)
<ul style="list-style-type: none"> • Exacerbating factors addressed • Near optimal volume status observed • Transition from intravenous to oral diuretic successfully completed • Patient and family education completed, including clear discharge instructions • LVEF documented • Smoking cessation counseling initiated • Near optimal pharmacologic therapy achieved, including ACE inhibitor and beta blocker (for patients with reduced LVEF), or intolerance documented • Follow-up clinic visit scheduled, usually for 7-10 days later
Interventions to Be Considered for Patients with Advanced HF or Recurrent Admissions for HF
<ul style="list-style-type: none"> • Oral medication regimen stable for 24 hours • No intravenous vasodilator or inotropic agent for 24 hours • Ambulation before discharge to assess functional capacity after therapy • Plans for postdischarge management (scale present in home, visiting nurse or telephone follow-up generally no longer than 3 days after discharge) • Referral for disease management, if available

Modified from Heart Failure Society of America, Lindenfeld J, Albert NM, et al: HFSA 2010 Comprehensive Heart Failure Practice Guideline. *J Card Fail* 16:e1, 2010.

Pharmacologic therapies known to improve long-term outcomes in chronic heart failure, such as use of beta blockers, ACE inhibitors, and mineralocorticoid receptor antagonists, should be initiated as soon as reasonable during the hospitalization and before discharge in hemodynamically stable, appropriate patients. Predischage initiation of a beta blocker increases the proportion of patients on appropriate therapy at 60 days and also may reduce 60- to 90-day mortality.⁶⁰ The Heart Failure Society of America (HFSA) guidelines provide specific criteria for considerations regarding hospital discharge (Table 24-4).⁵⁸

Phase IV: Postdischarge Management

Early recurrence of signs and symptoms of heart failure suggestive of worsening volume overload and/or neurohormonal activation is likely to contribute to the high rates of readmission that are observed for AHF.⁶⁷ Prompt interventions may therefore allow prevention of the progression of volume overload and limit new admissions. At least some rehospitalizations for heart failure appear to be preventable.⁶⁸ A series of studies also have investigated the benefits of postdischarge support, especially patient-centered discharge instructions, transition coaches, follow-up telephone calls, and early physician follow-up evaluation, although results of these studies have been mixed in terms of impact on outcomes.^{69,70} A follow-up appointment is optimally scheduled within approximately 7 to 10 days after discharge, but an earlier follow-up visit (in less than a week) should be considered for patients with high-risk features.

General Approaches to Therapy of Acute Heart Failure Targeting Congestion

Treatment strategies for AHF have been largely empirical and limited by an incomplete understanding of the epidemiology and pathophysiology, as well as the relatively blunt nature of the available therapeutic tools. The current general approach focuses on the successful treatment of clinical and hemodynamic congestion, while limiting untoward effects on myocardial or end-organ function, identifying addressable triggers, and optimizing proven long-term therapies. This approach incorporates information from three main aspects of the patient's clinical presentation: blood pressure, volume status, and renal function.

Blood Pressure

Blood pressure reflects the interaction between vascular tone and myocardial pump function and is one of the most important prognostic indicators in AHF (see earlier). Most patients present with elevated blood pressures and consequently will benefit from and safely tolerate vasodilator therapy. Vasodilators may decrease preload by reversing venous vasoconstriction and the related central volume redistribution from the peripheral and splanchnic venous systems, and reduce afterload by decreasing arterial vasoconstriction with a resultant improvement in cardiac and renal function. Vasodilators are the primary therapy for AHF with pulmonary edema, and for nonhypotensive patients with low cardiac output (poor peripheral or central perfusion with SBPs above 85 to 100 mm Hg). In an international registry of 4953 patients admitted for AHF (ALARM-HF) (75% admitted to ICU/CCU settings), analysis of data on a propensity-based matched cohort of 1007 matched pairs demonstrated improved in-hospital survival in patients treated with vasodilators and diuretics compared with patients treated only with diuretics, with 7.8% and 11.0% in-hospital mortality rates, respectively ($P = .016$).⁷¹ Of interest, this difference in survival was particularly evident in patients with SBP less than 120 mm Hg (Fig. 24-8). The selection of agent depends on the clinical situation, local practice, and availability (see later section on specific therapies).

Hypotension (SBP below 85 to 90 mm Hg) is a poor prognostic sign in patients with AHF. Treating the potentially reversible, underlying causative disorders, such as ACS, pulmonary embolus, and (rarely)

hypovolemia, is essential. Hypovolemic hypotension, usually related to overdiuresis, is unusual in patients with symptomatic AHF, and unappreciated volume overload may be present, especially in obese patients, in whom neck veins and ascites are difficult to assess. With clear evidence of hypovolemia, carefully monitored “fluid challenges” may be attempted, although rapidly given intravenous fluid boluses can precipitate congestive symptoms. Asymptomatic hypotension, as an isolated finding in the absence of congestion and poor peripheral or central perfusion, does not require emergent treatment. Inotropic therapy may be indicated for persistent symptomatic hypotension or evidence of hypoperfusion in the setting of advanced systolic dysfunction. An analysis of 954 propensity-matched pairs of patients from the ALARM-HF registry suggested that IV catecholamine use was associated with a 1.5-fold increase in in-hospital mortality for dopamine or dobutamine use and a greater than 2.5-fold increase for norepinephrine or epinephrine use.⁷¹ Specific inotropic agents vary by country and local clinical practice (see later section on specific agents). In most patients, invasive pulmonary artery catheter monitoring is not necessary, because the measures of urine output, blood pressure, and end-organ function can be clinically evaluated. In general, the use of vasoconstrictors, such as high-dose dopamine, phenylephrine, epinephrine, and norepinephrine, should be avoided unless such agents are absolutely necessary for management of refractory symptomatic hypotension or hypoperfusion. Rarely, overdosage of afterload-reducing agents can precipitate admission for AHF with a clinical presentation similar to that in

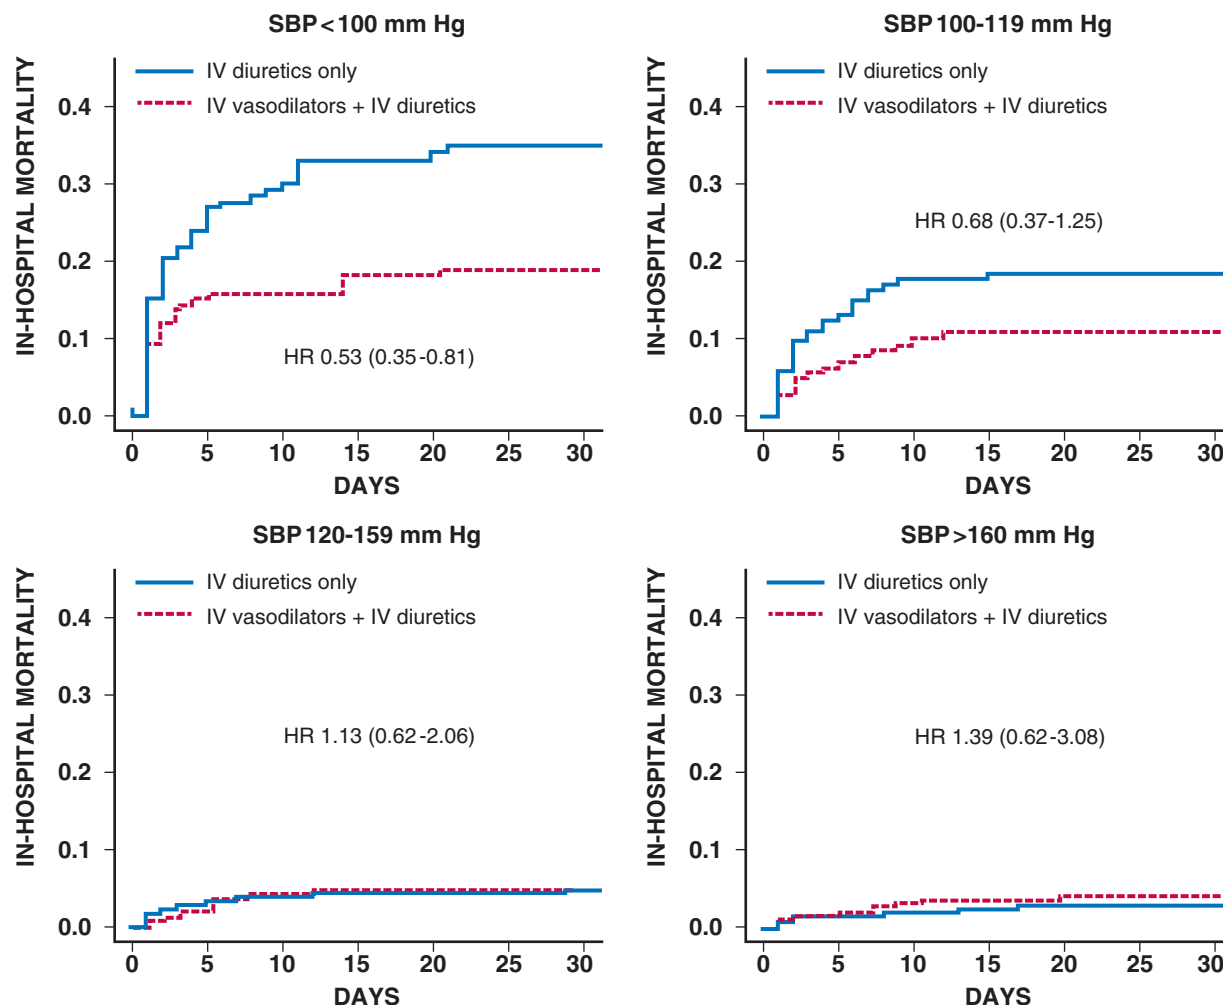

FIGURE 24-8 Effects of intravenous (IV) vasodilators on in-hospital mortality in patients with various levels of SBP. SBP values ranged from <100 to ≥ 160 mm Hg. The numbers of patients are 318, 334, 668, and 694 for SBP <100, 100-119, 120-159, and ≥ 160 mm Hg, respectively. HR = hazard ratio. Value in parentheses is the 95% confidence interval. (From Mebazaa A, Parissis J, Porcher R, et al: Short-term survival by treatment among patients hospitalized with acute heart failure: The global ALARM-HF registry using propensity scoring methods. *Intensive Care Med* 37:290, 2011.)

cardiogenic shock or “pseudosepsis,” in which case careful administration of vasoconstrictors may be indicated.

Volume Status

Most patients with AHF have evidence of volume overload, and for those patients in whom this is the dominant presenting feature, such as those with significant peripheral edema or ascites, intravenous diuretics remain the foundation of AHF therapy. Patients with clinically evident congestion typically have 4 to 5 liters of excess volume, and amounts greater than 10 L are not uncommon. The choice of diuretic regimen is influenced by the amount and rapidity of the desired fluid removal and the renal function (see further on). Diuresis addresses the underlying abnormality and frequently alleviates symptoms and signs of elevated filling pressures. However, intravenous vasodilator therapy may provide more rapid relief in highly symptomatic patients with evidence of pulmonary congestion. In fact, many patients with hypertensive AHF may require minimal diuretics. Careful attention to volume status is critical, because patients' symptoms of congestion may resolve despite persistent hemodynamic congestion (i.e., elevated filling pressures). Hospital discharge before hemodynamic congestion is fully treated appears to be a common cause of rehospitalization.⁷²

Renal Function

Renal function (see Chapter 88) is the third main aspect of a contemporary approach to treatment of the patient with AHF. Treatment of AHF in the presence of normal renal function is generally uncomplicated. Diuretics may be given in standard doses, although renal function, electrolytes, and volume status must be carefully monitored. However, approximately two thirds of patients present with at least moderate renal insufficiency.²² This deficit may reflect preexisting kidney disease or may be a manifestation of the worsening heart failure. Abnormal renal function typically is associated with some degree of diuretic resistance, and higher doses of diuretics or other strategies may be needed (see later section on diuretics). The important clinical problem of worsening renal function during AHF therapy, the cardiorenal syndrome, was discussed previously.

Invasive Hemodynamic Strategy

An invasive hemodynamic management with pulmonary artery catheterization (PAC) may be a useful strategy in the management of some patients with AHF. PAC is an invasive procedure that provides detailed hemodynamic data, including direct assessment of filling pressures and cardiac output, and calculation of pulmonary and systemic vascular resistance. Potential risks of PAC include bleeding, infection, arrhythmias, and rare catastrophic events, such as pulmonary artery rupture or infarction. The use of PAC in the routine management of AHF has been a subject of controversy.

The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) was a randomized controlled trial of 433 patients with severe symptomatic heart failure despite recommended therapies randomized to receive therapy guided by clinical assessment and PAC or by clinical assessment alone.⁷³ In ESCAPE, use of PAC did not significantly affect the days alive and out of hospital during the first 6 months (133 versus 135 days), mortality (43 versus 38 deaths), or the number of days hospitalized (8.7 versus 8.3 days) compared with clinical assessment alone. Based on the results of the ESCAPE trial, the use of PAC in AHF management has declined—in EHFS II, only 5% of patients underwent PAC during AHF hospitalization. Of note, the ESCAPE study excluded patients in whom the treating clinician did not have equipoise about the need for invasive hemodynamic measurement. Invasive hemodynamic assessment with PAC may still play an important role in selected patients, especially those with shock or other severe hemodynamic compromise or with oliguria or anuria, or those with unclear hemodynamics and poor response to therapy. In patients with advanced heart failure in whom PAC is used to tailor therapy, an LV filling pressure as approximated by PCWP of less than 16 mm Hg, right atrial pressure less than 8 mm Hg, and systemic vascular resistance between 1000 to 1200 dynes-sec/cm⁻⁵ are useful targets.⁷⁴

Process of Care, Outcomes, and Quality Assessment

The first point of contact at the admitting hospital for most patients (80%) is the emergency department. Once the patient with AHF is hospitalized, there appear to be substantial geographic differences in process of care and hospital course worldwide.⁷⁵ In the U.S. ADHERE registry, 23% of patients were admitted to an ICU setting, whereas a substantially higher proportion (51%) had an ICU stay in a similar European registry (EHFS II). Median length of stay also is markedly different across geographic regions, with length of stay in the United States being approximately 4 days, almost twice that in Europe (median of 9 days in EHFS II), and even higher in Japan (21 days in the ATTEND registry). These differences in length of stay do not appear to be fully explained by differences in case mix or severity of illness. The longer length of stay outside the United States generally is associated with lower rates of short-term rehospitalization, although a cause-and-effect relationship is not fully established. A substantial focus on reducing length of stay in the United States appears to have been accompanied by an increase in postdischarge events, both mortality and (in particular) rehospitalization, as described in more detail next.⁷⁶ In general, the natural history of AHF is characterized by relatively low in-hospital mortality but a high rate of recurrent postdischarge events (Table 24-5). Inpatient mortality rates for patients with AHF range between 3% and 7%, with the notable exception of patients in cardiogenic shock, who have a markedly increased in-hospital mortality (40% in EHFS II).¹⁰ Although in-hospital mortality is low, hospitalization for AHF portends a substantial worsening of the clinical course in many cases. In the EVEREST study, despite careful attention to evidence-based care in the context of a large clinical trial, 26% of enrolled patients died during a median follow-up period of 9.9 months. Of all deaths, 41.0% were due to heart failure, 26.0% due to sudden cardiac death, 2.6% due to acute myocardial infarction, 2.2% due to stroke, and 13.2% due to noncardiovascular causes.⁷⁷

The Rehospitalization Problem

The high rates of rehospitalization after discharge from a heart failure hospitalization have become a major focus of clinicians, policy makers, and payers. Claims data using the U.S. Medicare sample suggest striking rates of rehospitalization in elderly patients, with a 30-day rehospitalization rate of 27%, although rates are substantially lower in younger, non-Medicare cohorts.^{78,79} Rates of rehospitalization within 6 months approach 50% in many cohorts, in particular older adults. Of note, approximately half of the rehospitalizations are not heart failure-related, which underscores the total burden of comorbidity in patients with heart failure as well as the challenges in affecting this event rate with heart failure-focused interventions. In the EVEREST study, careful adjudication of postdischarge hospitalizations showed that 46% were for heart failure, 15% for other cardiovascular causes, and 39% were for noncardiovascular causes.⁷⁷ These rehospitalizations represent a major driver of health expenditures, accounting for 21 billion of the \$39 billion spent on heart failure care per year in the United States.¹ Although controversial, reducing rehospitalization rates for heart failure has been identified as a major focus of quality improvement and cost containment by payers such as the U.S. Centers for Medicare & Medicaid Services. As a result, a variety of interventions and initiatives related to inpatient management, discharge planning, and transitions of care have been implemented in an attempt to decrease rehospitalization rates for heart failure, although the nature, implementation, and effectiveness of these practices have varied widely across health systems.⁸⁰ Also uncertain is what proportion of rehospitalizations are avoidable, although a recent systematic review suggests that a quarter or more may be preventable.⁶⁸ To date, only improved use of proven evidence-based therapies (such as beta blockers and ACE inhibitors) during acute hospitalization has been shown to improve postdischarge outcomes.⁶⁴ Hospital discharge before congestion is adequately treated appears to be a common cause of early readmission.⁷² Early postdischarge follow-up evaluation also has been associated with lower rehospitalization rates in retrospective registry data.⁷⁰ A variety of

TABLE 24-5 Outcomes in Patients with Acute Heart Failure from Selected Trials and Registries

other interventions centered on telemedicine, disease monitoring, and disease management remain under active investigation.

Specific Therapies for Acute Heart Failure

Diuretics

Loop diuretics are the primary pharmacologic agents for treatment of volume overload in patients with AHF and typically produce rapid symptom relief in most patients.⁸¹ (Diuretics are discussed in detail in [Chapter 25](#).) This group of agents (furosemide, torsemide, bumetanide, and ethacrynic acid) ([Table 24-6](#)) can lead to excretion of up to 25% of the filtered sodium and intravenous administration avoids variable bioavailability and allows for rapid onset of action (typically within 30 to 60 minutes). Based on the results of the DOSE study described further on, initial doses of approximately 2.5 times the outpatient dose should be considered for patients on chronic oral diuretic therapy, with underlying renal dysfunction, or with severe volume overload. In view of the steep dose-response curve of these agents, titration should be rapid with doubling of the dose until an effective response is noted. With significant volume overload (>5 to 10 liters) or diuretic resistance, a continuous intravenous infusion can be considered.

Despite their ubiquitous use in AHF, loop diuretics have generally not been tested in rigorously controlled clinical trials. Loop diuretics may lead to neurohormonal activation and electrolyte repletion and have been associated in observational studies with both increased risk of worsening renal function and decreased survival.⁸² The DOSE trial was the first large, randomized, double-blind trial to prospectively compare diuretic strategies in AHF.⁸³ Using a 2 × 2 factorial design, 308 patients were randomly assigned to treatment with intravenous furosemide using either twice-daily bolus dosing or a continuous infusion and to either a low-dose (equivalent to the numerical value of the oral outpatient dose given IV) or high-dose (2.5 times the oral dose given IV) strategy. No significant difference was documented in either of the coprimary endpoints of global assessment of symptoms and change in creatinine at 72 hours with administration by bolus compared with infusion or with the low- versus high-dose

strategy. The high-dose strategy was associated with greater relief of dyspnea and net fluid loss at 72 hours, although more patients in the high-dose group exhibited a transient increase in creatinine, of less than 0.3 mg/dL, which resolved by the time of hospital discharge ([Table 24-7](#)). The significance of this finding is unclear; although there were no apparent differences in hospital length of stay or days alive out of the hospital, the study was not powered for long-term clinical outcomes. Overall, no differences were found in results between the continuous infusion and intermittent bolus strategies in the clinical trial setting of DOSE, suggesting that whichever approach is most likely to reliably produce the desired diuresis in the particular local clinical practice should be used.

In the setting of diuretic resistance, administration of a thiazide-like diuretic that blocks the distal tubule can provide significant augmentation of the diuretic effect.⁸⁴ Intravenous chlorothiazide (500 to 1000 mg) or oral metolazone (2.5 to 10 mg) given before the loop diuretic are effective agents, although care must be taken to monitor for hypotension, worsening renal function, and electrolyte abnormalities, which may be profound. Nonsteroidal anti-inflammatory drugs can greatly reduce the efficacy of diuretics, as well, by reducing renal synthesis of vasodilatory prostaglandins, and these agents should be avoided. If hypokalemia is a persistent problem with marked replacement requirements, administration of a potassium-sparing diuretic, such as spironolactone or eplerenone, should be considered and also may provide synergistic diuretic effects, especially at higher doses.⁸⁵

Vasodilators

In the absence of hypotension, vasodilators can be used as first-line agents in combination with diuretics in the management of patients with AHF to improve congestive symptoms ([Table 24-8](#)).⁸⁶ As noted previously, in the ALARM-HF registry using propensity-matching techniques, patients admitted with AHF and treated with diuretics and vasodilators had significantly better in-hospital survival compared with patients treated with diuretics alone or those treated with inotropes.⁷¹ Vasodilators can be classified as (1) predominantly venous dilators, with consequent reduction in preload; (2) arterial dilators, leading to a decrease in afterload; and (3) balanced vasodilators,

TABLE 24-6 Therapeutic Approaches for Volume Management in Acute Heart Failure

SEVERITY OF VOLUME OVERLOAD	DIURETIC/ DEVICE	DOSE (MG)	COMMENTS
Moderate	Furosemide	20-40 or up to 2.5 times oral dose	Intravenous administration preferable in symptomatic patients
	OR Bumetanide	0.5-1.0	Titrate dose according to clinical response
	OR Torsemide	10-20	Monitor Na ⁺ , K ⁺ , creatinine, blood pressure
Severe	Furosemide	40-160 or 2.5 times oral dose 5-40 mg/hr infusion	Intravenously
	OR Bumetanide	1-4/0.5-2 mg/hr infusion (max 2-4 mg/hr, limit 2-4 hr)	Bumetanide and torsemide have higher oral bioavailability than furosemide, but intravenous administration preferable in AHF
	OR Torsemide	20-100/5-20 mg/hr	
	Ultrafiltration	200-500 ml/hr	Adjust ultrafiltration rate to clinical response, monitor for hypotension; consider hematocrit sensor
Refractory to loop diuretics	Add HCTZ	25-50 twice daily	Combination with loop diuretic may be better than very high dose of loop diuretics alone
	OR Metolazone	2.5-10 once daily	Metolazone more potent if creatinine clearance <30 mL/min
	OR Chlorothiazide	250-500 IV	
		500-1000 PO	

HCTZ = hydrochlorothiazide.

with combined action on both the venous and the arterial system. Currently available vasodilators include the organic nitrates (nitroglycerin [NTG] and isosorbide dinitrate), sodium nitroprusside (SNP), and nesiritide. All of these drugs act by activating soluble guanylate cyclase (sGC) in the smooth muscle cells, leading to higher intracellular concentrations of cyclic guanosine monophosphate (cGMP) and consequent vessel relaxation (see Chapter 22). They should be used with caution in patients who are preload- or afterload-dependent (e.g., severe diastolic dysfunction, aortic stenosis, coronary artery disease), because they may cause severe hypotension. Blood pressure (BP) should be monitored frequently and the drug discontinued if symptomatic hypotension develops.

Nitrates

Organic nitrates are one of the oldest therapeutic agents for management of AHF. These agents are potent venodilators, producing rapid decreases in pulmonary venous and ventricular filling pressures and improvement in pulmonary congestion, dyspnea, and myocardial

oxygen demand at low doses. At slightly higher doses and in the presence of vasoconstriction, nitrates also are arteriolar vasodilators, reducing afterload and increasing cardiac output. Nitrates are relatively selective for epicardial, compared to intramyocardial, coronary arteries, resulting in increased coronary blood flow and making them useful for patients with concomitant active myocardial ischemia. The starting dose of nitroglycerin usually is 20 µg/min with rapid up-titration occurring every 5 to 15 minutes in either 20-µg/min increments or doubling of the dose. The dose may initially be titrated to the goal of immediate symptom relief, but a blood pressure reduction of at least 10 mm Hg in mean arterial pressure with a SBP greater than 100 mm Hg may be preferable. The nitrate dose may need to be reduced if SBP is 90 to 100 mm Hg and often will need to be discontinued with SBP below 90 mm Hg. Intravenous nitrate use appears to be more common in Europe than in the United States (38% in EHFS II but only 9% in ADHERE).^{10,53} Organic nitrates may also be administered orally, sublingually, or by spray, allowing for convenient emergent treatment before establishing intravenous access.

TABLE 24-8 Intravenous Vasoactive Agents for the Treatment of Acute Heart Failure

INTRAVENOUS MEDICATION	INITIAL DOSE	EFFECTIVE DOSE RANGE	COMMENTS
Vasodilators			
Nitroglycerin; glyceryl trinitrate	20 µg/min	40-200 µg/min	Hypotension, headache; tolerance with continuous use after 24 hours
Isosorbide dinitrate	1 mg/h	2-10 mg/h	Hypotension, headache; tolerance with continuous use within 24 hours
Nitroprusside	0.3 µg/kg/min	0.3-5 µg/kg/min (usually <4 µg/kg/min)	Caution in patients with active myocardial ischemia; hypotension; cyanide side effects (nausea, dysphoria); thiocyanate toxicity; light sensitivity
Nesiritide	2 µg/kg bolus with 0.010-0.030 µg/kg/min infusion	0.010-0.030 µg/kg/min	Uptitration: 1 µg/kg bolus, then increase infusion rate by 0.005 µg/kg/min no more frequently than every 3 h, up to a maximum of 0.03 µg/kg/min Hypotension, headache (less than with organic nitrates)
Inotropes			
Dobutamine	1-2 µg/kg/min	2-20 µg/kg/min	For inotropy and vasodilation; hypotension, tachycardia, arrhythmias; ?mortality
Dopamine	1-2 µg/kg/min	2-4 µg/kg/min	For inotropy and vasodilation; hypotension, tachycardia, arrhythmias; ?mortality
	4-5 µg/kg/min	5-20 µg/kg/min	For inotropy and vasoconstriction; tachycardia, arrhythmias; ?mortality
Milrinone	25-75 µg/kg bolus* over 10-20 min followed by infusion	0.10-0.75 µg/kg/min	For vasodilation and inotropy; hypotension, tachycardia, arrhythmias; renal excretion; ?mortality
Enoximone [†]	0.5-1 mg/kg	5-20 µg/kg/min	For vasodilation and inotropy; hypotension, tachycardia, arrhythmias; ?mortality
Levosimendan [†]	12 µg/kg bolus over 10 min followed by infusion	0.1-0.2 µg/kg/min	For vasodilation and inotropy; active metabolite present for ~84 hr; hypotension, tachycardia, arrhythmias; ?mortality
Epinephrine		0.05-0.5 µg/kg/min	For vasoconstriction and inotropy; tachycardia, arrhythmias, end-organ hypoperfusion; ?mortality
Norepinephrine		0.2-1.0 µg/kg/min	For vasoconstriction and inotropy; tachycardia, arrhythmias, end-organ hypoperfusion; ?mortality

*Some clinicians do not administer a bolus dose, so as to decrease the risk of hypotension. Bolus not recommended in patients with hypotension.

[†]Not approved for use in all countries.

Clinical trial experience with organic nitrates is limited.⁸⁶ Early administration of high-dose intravenous nitrates is beneficial in improving arterial oxygenation and potentially preventing some consequences of AHF (myocardial infarction, need for mechanical ventilation), compared with furosemide alone⁵⁵ or noninvasive ventilation,⁸⁷ although these studies were small and not blinded. In a study designed to evaluate nesiritide in patients with dyspnea at rest from decompensated heart failure, nitroglycerin treatment in 143 patients demonstrated nonsignificant, mild decreases in PCWP and no significant improvement in patient-assessed dyspnea within 3 hours, but the dose was remarkably low (42 µg/min).⁸⁸ In a small, single-site substudy⁸⁹ where nitroglycerin was aggressively uptitrated to a mean dose of 155 µg/min by 3 hours, significant decreases were observed in PCWP (4 to 6 mm Hg decrease from baseline) from 1 to 12 hours but no difference was noted at 24 hours. The major limitation of organic nitrates is the tolerance that typically develops within 24 hours. Headache is the most common adverse effect (occurring in 20% of patients within 24 hours⁸⁸). Symptomatic hypotension (5%) also may be noted but generally resolves when nitrate therapy is discontinued. In view of the risk of severe hypotension with potentially catastrophic consequences, the recent use of phosphodiesterase-5 inhibitors (sildenafil, tadalafil, and vardenafil) should be ruled out before administration of nitrates.

Sodium Nitroprusside

SNP induces a balanced reduction in afterload and preload that is exquisitely titratable, owing to a very short half-life (seconds to a few minutes) and is particularly effective in the setting of markedly elevated afterload (e.g., hypertensive AHF) and moderate to severe mitral

regurgitation. Intravenous administration usually is monitored with an indwelling arterial line, although automated blood pressure cuffs are now used in many centers. Titration of the SNP dose to rapidly improve symptoms and to achieve an SBP of 90 to 100 mm Hg are typical goals, and invasive pulmonary artery catheters may assist in meeting other hemodynamic goals. Tapering the dose of nitroprusside before discontinuation is advised, to avoid the possibility of “rebound hypertension.” Physician discomfort with the cyanide metabolites and the historical institutional requirements for invasive arterial monitoring has limited the use of this highly effective therapy to less than 1% of patients with AHF in Europe and the United States.^{10,53}

Nitroprusside, a prodrug that is rapidly metabolized to nitric oxide and cyanide, has no inherent arrhythmogenic properties, may decrease myocardial oxygen demand by reducing afterload and wall stress, creates no significant electrolyte disturbances, and is rarely toxic. Despite its potency, severe hypotension is unusual and rapidly resolves. However, significant vasodilation of the intramyocardial vasculature has been noted, possibly producing a coronary steal phenomenon; consequently, nitroprusside is not recommended for patients with active myocardial ischemia. The most common complaints with nitroprusside are related to the cyanide metabolite, including nausea, abdominal discomfort, dissociative feelings, and dysphoria. Cyanide rarely accumulates in patients, but impaired hepatic function and doses greater than 250 µg/min for longer than 48 hours increase this risk. The thiocyanate metabolite can accumulate in patients with

moderate to severe renal insufficiency who receive prolonged infusions of high doses (usually >400 µg/min) over days and usually is not relevant in the treatment of AHF. Cyanide levels may be measured, but results rarely return in a timely fashion to be useful.

No randomized studies of nitroprusside in patients with AHF have been performed, although multiple studies demonstrated dramatic reduction in PCWP (15 mm Hg) and marked increases in cardiac output, associated with increases in diuresis and natriuresis, and decreased neurohormonal activation. In a contemporary analysis of data on 175 consecutive patients hospitalized for AHF, intravenous SNP was associated with greater hemodynamic improvement and lower rates of inotropic support or worsening renal function during hospitalization and with lower rates of all-cause mortality after discharge, despite a worse hemodynamic profile at baseline.⁹⁰

Nesiritide

Nesiritide (recombinant human B-type [brain] natriuretic peptide) is identical to endogenous BNP and causes potent vasodilation in the venous and arterial vasculatures, resulting in significant reductions in venous and ventricular filling pressures and mild increases in cardiac output. As with other vasodilators, nesiritide may reduce diuretic requirements, but in clinical studies, the evidence for a significant direct “natriuretic” effect is limited. Nesiritide may be used for treatment of patients with acutely decompensated congestive heart failure who have dyspnea at rest or with minimal activity, but it should not be administered for the indication of replacing diuretics, enhancing diuresis, protecting renal function, or improving survival. An optional bolus of 2 µg/kg followed by a 0.01 µg/kg/min infusion is the recommended starting dose for nesiritide. Clinical trial experience with up-titration of the drug is limited, but for patients who remain symptomatic with evidence of volume overload and sufficient blood pressure, up-titration may be considered. Nesiritide has clear effects on hemodynamics and has limited need for frequent dose adjustments and an absence of tolerance, but its high cost and lack of clear clinical benefit beyond other less expensive and more readily titratable agents have limited its use.

The Vasodilation in the Management of Acute CHF (VMAC) trial randomly assigned 489 patients with decompensated chronic heart failure and dyspnea at rest to receive placebo, nitroglycerin, or nesiritide.⁸⁸ After 3 hours, patients receiving nesiritide had a significantly greater decrease in PCWP compared with both nitroglycerin and placebo, and improvement in dyspnea compared with placebo (no difference from nitroglycerin). A pooled analysis of the randomized, controlled clinical trial data suggested that nesiritide may be associated with an increased risk of worsening renal function⁹¹ as well as increased mortality.⁹² To address these issues, the ASCEND-HF trial randomly assigned 7141 patients with AHF to receive either nesiritide or placebo for 24 to 168 hours.⁹³ At 30 days, no difference was observed between patients receiving nesiritide and those receiving placebo with regard to the composite endpoint of death or rehospitalization for heart failure. The clinical effects on dyspnea were relatively modest and have generally not been thought to be clinically important compared to placebo (Fig. 24-9). Use of nesiritide had no impact on worsening renal function but was associated with an increase in the rate of hypotension.

Nesiritide exerts its activity by means of guanylyl cyclase-linked natriuretic peptide receptors (NPR A and NPR B), causing cGMP-mediated vasodilation (see also Chapter 22). Hypotension, at times prolonged (lasting longer than 2 hours⁸⁸) despite the relatively short (18-minute) half-life of the peptide, is more common in patients with volume depletion; consequently, nesiritide use should be limited to those with congestive signs and symptoms. Headache also occurs, although less frequently than with nitroglycerin. Other actions of nesiritide include neurohormonal antagonism with reduction in vasopressin, aldosterone, and sympathetic tone, and alteration of intrarenal hemodynamics and glomerular filtration. Nesiritide did not improve urine output or renal function in patients with AHF in whom creatinine levels were increasing.⁹⁴

Inotropes and Inodilators

The inotropic drugs and inodilators (inotropic drugs with vasodilatory properties) increase cardiac output through cyclic adenosine

SELF-ASSESSED CHANGE IN DYSPNEA AT 6 AND 24 HOURS

DEATH FROM ANY CAUSE OR REHOSPITALIZATION FOR HEART FAILURE AT 30 DAYS

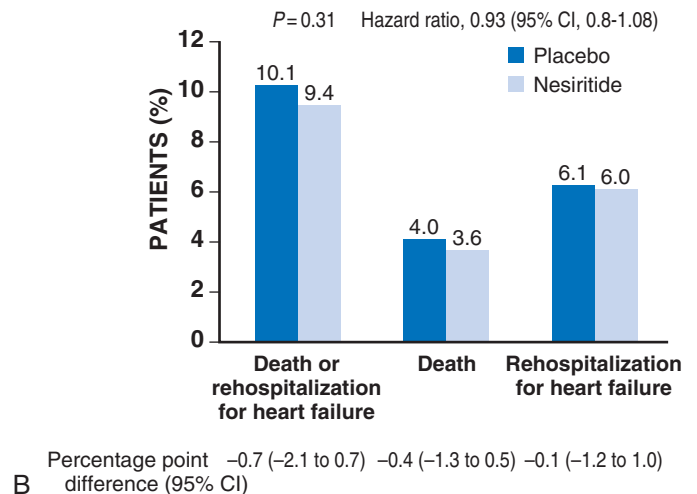

FIGURE 24-9 Changes in dyspnea at 6 and 24 hours (A) and the primary clinical endpoints at 30 days (B). In A, the number above the bar indicates the overall percentage of patients who reported being markedly or moderately better after receiving study treatment (i.e., those represented by the percentages above the dashed line). (From O'Connor CM, Starling RC, Hernandez AF, et al: Effect of nesiritide in patients with acute decompensated heart failure. *N Engl J Med* 2011;365:32, 2011.)

monophosphate (cAMP)-mediated inotropy and reduce PCWP through vasodilation⁹⁵ (Table 24-8). However, retrospective data from both registries and trials of AHF patients suggest that even the short-term use (hours to few days) of intravenous inotropes (except for digoxin) is associated with significant side effects such as hypotension, atrial or ventricular arrhythmias, and an increase in in-hospital⁷¹ and possibly long-term mortality.⁹⁶ Patients with coronary artery disease may be at higher risk for adverse events owing to their reduced coronary perfusion and increased myocardial oxygen requirements with possible myocardial ischemia and injury. Therefore these agents are reserved for use in selected situations of hypoperfusion when other interventions are inappropriate or have failed. The use of these drugs should be limited to patients with dilated ventricles and reduced ejection fraction who present with low SBP (<90 mm Hg) or low measured cardiac output in the presence of signs of congestion and organ hypoperfusion such as decreased mentation and reduced urine output.⁵⁸ Inotropic agents for AHF should be used with close hemodynamic and telemetry monitoring

and should be stopped as soon as adequate organ perfusion is restored. All of these agents may increase conduction through the atrioventricular node, causing a rapid ventricular response in patients presenting with atrial fibrillation. Additionally, intravenous inotropes may be used in cardiogenic shock as a temporary therapy to prevent hemodynamic collapse or as a life-sustaining bridge to more definitive therapy for those patients awaiting mechanical circulatory support, ventricular assist devices, or cardiac transplantation. In North American and European registries, approximately 15% and 25% of patients, respectively, were treated with inotropic agents, although in view of the minimal supportive clinical evidence, marked local variability in the use of these drugs is likely.⁹⁷

Dobutamine

Dobutamine is the most commonly used positive inotrope in Europe and the United States, despite evidence that it increases mortality.^{98,99} Many patients will experience improved renal perfusion with dobutamine doses of 1 to 2 $\mu\text{g/kg/min}$, although higher doses (5 to 10 $\mu\text{g/kg/min}$) may be necessary for those with more profound hypoperfusion. Tachyphylaxis may occur with infusions lasting longer than 24 to 48 hours, owing in part to receptor desensitization. In general, dobutamine (or dopamine) is the preferred inotrope in patients with significant hypotension and in the setting of significant renal dysfunction, in keeping with the renal excretion of milrinone. Concomitant beta blocker therapy will result in competitive antagonism of the effects of dobutamine, and higher doses of dobutamine (10 to 20 $\mu\text{g/kg/min}$) may be required to obtain the desired hemodynamic effects. The lowest effective dose of dobutamine should be used, supported by continuous blood pressure and rhythm monitoring. The patient should be gradually weaned off dobutamine and clinical status reevaluated with each dose adjustment. Temporary adjustments to afterload-reducing agents or diuretics may assist in weaning.

As an agonist of both β_1 and β_2 adrenergic receptors (see Chapter 21) with variable effects on the α receptors, dobutamine has multiple actions. Beta receptor stimulation results in increased inotropy and chronotropy through increases in intracellular cAMP and calcium, as well as through direct activation of voltage-sensitive calcium channels. At low doses, stimulation of β_2 and α receptors causes vasodilation, resulting in decreased aortic impedance and systemic vascular resistance with reduction in afterload and indirect increases in cardiac output. At higher doses, vasoconstriction can ensue, with decreased venous capacitance and increased right atrial pressure. Adverse effects of dobutamine include tachycardia, increasing ventricular response to atrial fibrillation, increased atrial and ventricular arrhythmias, myocardial ischemia, and possibly cardiomyocyte necrosis mediated by direct toxic effects and induction of apoptosis.¹⁰⁰

Although the hemodynamic and other effects of dobutamine have been studied, only one placebo-controlled, randomized trial has been conducted in patients with AHF. Although some methodologic concerns were raised, the CASINO ("Calcium Sensitizer or Inotrope or NOne in low output heart failure") study demonstrated significantly increased mortality with dobutamine compared with placebo, consistent with the results of other studies of this class of agents.⁹⁸

Dopamine

In both the United States and Europe, dopamine is used as often as dobutamine, presumably as a vasoconstrictor and for its putative effects on renal vasodilation. As a precursor to the synthesis of norepinephrine, an agonist of both adrenergic and dopaminergic receptors, and an inhibitor of norepinephrine uptake, dopamine has complex effects that vary significantly with dose. Initiation of dopamine therapy causes a rapid release of norepinephrine that can precipitate tachycardia, as well as atrial and ventricular arrhythmias. In addition, intermediate to high doses can cause significant vasoconstriction, precipitating heart failure and poor perfusion. Dopamine dosing should be gradually decreased from these doses down to 3 to 5 $\mu\text{g/kg/min}$ and then discontinued, to avoid potential hypotensive effects of low-dose dopamine.

Low-dose dopamine ($\leq 2 \mu\text{g/kg/min}$) has been proposed to cause selective dilation of renal, splanchnic, and cerebral arteries, potentially

increasing renal blood flow in a selective manner, as well as promoting natriuresis through direct distal tubular effects. A meta-analysis suggests that low-dose dopamine may increase urine output on the first day, associated with no effect on creatinine clearance and a trend toward increased adverse events.¹⁰¹ The DAD-HF study of 60 patients hospitalized for AHF suggested that a combination of low-dose furosemide and low-dose dopamine resulted in comparable urine output and dyspnea relief but improved renal function profile and potassium homeostasis compared with high-dose furosemide.¹⁰² In contrast, the ROSE trial^{102a} of 241 patients with acute heart failure and renal dysfunction showed that low-dose dopamine did not enhance decongestion nor improve renal function when added to diuretic therapy. If low-dose dopamine therapy is initiated, it should be discontinued in the event of no response.

Intermediate-dose dopamine (2 to 10 $\mu\text{g/kg/min}$) results in enhanced norepinephrine release, stimulating cardiac receptors with an increase in inotropy and mild stimulation of peripheral vasoconstricting receptors. Because the positive inotropic effect is largely dependent on myocardial catecholamine stores, which often are depleted in patients with advanced heart failure, dopamine is a poor inotrope in patients with severe systolic dysfunction.

High-dose dopamine (10 to 20 $\mu\text{g/kg/min}$) causes peripheral and pulmonary artery vasoconstriction, mediated by direct agonist effects on α -adrenergic receptors. These doses carry a significant risk of precipitating limb and end-organ ischemia and should be used cautiously.

Epinephrine

Epinephrine is a full beta receptor agonist and a potent inotropic agent with balanced vasodilator and vasoconstrictor effects. The direct effect of epinephrine on increasing inotropy independent of myocardial catecholamine stores makes it a useful agent in the treatment of transplant recipients with denervated hearts.

Phosphodiesterase Inhibitors

Cyclic AMP is a ubiquitous signaling molecule that increases inotropy, chronotropy, and lusitropy in cardiomyocytes and causes vasorelaxation in vascular smooth muscle (see Chapter 21). Phosphodiesterase IIIa (PDE IIIa) is compartmentalized in the cardiac and vascular smooth muscle, where it terminates the signaling activity of cAMP by degrading it to AMP. Many specific inhibitors of PDE IIIa, such as milrinone and enoximone, have been developed to provide organ specific improvements in hemodynamics through increasing myocardial and vascular smooth muscle cell cAMP concentrations. Subcellular localization provides the possibility to stimulate inotropy without increasing heart rate with low doses of a highly specific phosphodiesterase inhibitor (PDEI). The independence of the mechanism from adrenergic receptors bypasses receptor downregulation, desensitization, and antagonism by beta blockers. Although studies have shown improved hemodynamic efficacy with PDEI compared with dobutamine in patients on beta blocker therapy, such limitations of dobutamine's effects typically are not clinically relevant. In addition, this mechanism allows for synergistic effects with beta receptor agonists such as dobutamine. Such combination therapy may be useful in patients with markedly reduced LV systolic function. PDEIs cause significant peripheral and pulmonary vasodilation, reducing afterload and preload, while increasing inotropy. These effects make them well suited for use in patients with LV dysfunction and pulmonary hypertension or in transplant recipients.

Milrinone is the most commonly used PDEI, but only 3% of patients in ADHERE⁵³ and less than 1% in EHFS II¹⁰ received it. Milrinone therapy may be initiated with a 25 to 75 $\mu\text{g/kg}$ bolus over 10 to 20 minutes, although in clinical practice the bolus dose often is omitted. Infusions typically are started at 0.10 to 0.25 $\mu\text{g/kg/min}$ and may be uptitrated to hemodynamic effect. Reflecting the elimination half-life of 2.5 hours and the pharmacodynamic half-life of more than 6 hours, effects from uptitration are delayed by at least 15 minutes after dosage adjustment. Also in keeping with these pharmacodynamics, patients who have had prolonged administration of milrinone may experience delayed deterioration, so they should be observed for at least 48 hours after cessation. Milrinone is renally excreted, necessitating dose adjustment in the presence of renal dysfunction or

substitution with dobutamine. Milrinone has many side effects, including hypotension and atrial and ventricular arrhythmias. In OPTIME-CHF (Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure),¹⁰³ 951 patients admitted with exacerbation of systolic heart failure not requiring intravenous inotropic support were randomly assigned to receive milrinone or placebo infusion. No difference was found in the primary endpoint of days hospitalized for cardiovascular causes within 60 days, but significant increases in sustained hypotension and new atrial arrhythmias were noted in the milrinone-treated patients. In addition, a post hoc subgroup analysis demonstrated increased mortality in patients with an ischemic cause of heart failure who received milrinone.⁹⁶ This study reinforces the need for caution in selecting these agents for the treatment of patients with AHF.

Enoximone. Enoximone also is a type IIIa PDEI that is available in Europe. Dosing is essentially one-tenth that of milrinone, with a bolus dose of 0.25 to 0.75 $\mu\text{g/kg}$ bolus over 10 to 20 minutes, followed by an infusion of 1.25 $\mu\text{g/kg/min}$. It is extensively metabolized by the liver into renally cleared active metabolites, so doses should be reduced in the setting of either renal or hepatic insufficiency. Otherwise, the foregoing comments apply to this PDEI as well.

Levosimendan. Levosimendan is a novel agent that increases myocardial contractility and produces peripheral vasodilation, through cardiac myofilament calcium sensitization by calcium-dependent (systolic) troponin C binding and activation of vascular smooth muscle potassium channels, respectively. Levosimendan also has some in vitro PDEI activity, presumably at concentrations higher than achieved in clinical use.¹⁰⁴ Levosimendan was administered to almost 4% of patients in EHFS II¹⁰ and is available in more than 40 countries (although not in the United States), where it is used in patients with reduced LV systolic function and hypoperfusion in the absence of severe hypotension. Although it may be given in a bolus of 12 to 24 $\mu\text{g/kg}$ over 10 minutes, many clinicians directly initiate a continuous infusion at a rate of 0.05 to 0.10 $\mu\text{g/kg/min}$, which may be uptitrated to 0.2 $\mu\text{g/kg/min}$. In clinical trials, levosimendan has been shown to significantly increase cardiac output, reduce PCWP and afterload, and decrease dyspnea. The potent vasodilating effects of levosimendan can cause significant hypotension, which may be avoided by maintaining filling pressures.⁹⁵ Levosimendan has an active, acetylated metabolite with a half-life of over 80 hours, so that it can continue to exert its hemodynamic effects days after discontinuation of the infusion.

Initial clinical studies demonstrated reduced arrhythmias and improved survival with levosimendan compared with placebo and dobutamine. REVIVE-II (Randomized multicenter Evaluation of Intravenous levosimendan Efficacy versus placebo in the short-term treatment of decompensated heart failure), a recent study of 600 patients, demonstrated significant improvement in clinical status, serial BNP levels, and hospital length of stay with levosimendan treatment compared with standard care, but also documented more episodes of hypotension, atrial fibrillation, and ventricular ectopy, as well as a nonsignificant increase in early deaths at 14 to 90 days.¹⁰⁵ The SURVIVE (Survival of Patients with Acute Heart Failure in Need of Intravenous Inotropic Support) trial randomly assigned 1327 patients with systolic dysfunction, evidence of low cardiac output, and dyspnea at rest despite diuretics and vasodilators to receive either levosimendan or dobutamine. An early reduction in mortality was not sustained through 180 days, but levosimendan was associated with a higher incidence of atrial fibrillation and lower incidence of worsening heart failure compared with dobutamine.¹⁰⁶

Vasopressors

Vasopressors should be reserved for patients with marked hypotension in whom central organ hypoperfusion is evident. These agents will redistribute cardiac output centrally at the expense of peripheral perfusion and increased afterload. **Phenylephrine** is a selective α_1 receptor agonist with potent direct arterial vasoconstrictor effects. This agent may be used in case of severe hypotension, particularly when the hypotension is related to systemic vasodilation, rather than to a decrease in cardiac output. **Norepinephrine** also is a potent agonist of the β_1 and the α_1 receptors but is a weaker agonist of β_2 receptors, resulting in marked vasoconstriction. Both of these agents may induce end-organ hypoperfusion and tissue necrosis.

Other Pharmacologic Therapies

Digoxin. Digoxin rapidly improves hemodynamics without increasing heart rate or decreasing BP and may be considered in patients

with a low BP resulting from a low cardiac output.¹⁰⁷ Digoxin may be used intravenously with an initial bolus of 0.5 mg IV. It should be given slowly because a rapid administration may cause systemic vasoconstriction. The initial bolus should be followed by an oral or IV dose of 0.25 mg at least 12 hours after the initial dose. In patients who continue to have signs and symptoms of heart failure, digoxin therapy should be continued in addition to other therapies, with a dose resulting in a trough serum concentration of less than 1 ng/mL. Ischemia, hypokalemia, and hypomagnesemia may increase the likelihood of developing digitalis intoxication, even at the therapeutic doses. Digoxin should not be used in patients with moderate to severe renal impairment, ongoing ischemia, or advanced atrioventricular block.

Arginine Vasopressin Antagonists. Arginine vasopressin (AVP), also known as antidiuretic hormone, is the main regulator of plasma osmolality. Vasopressin levels are inappropriately high in both acute and chronic forms of heart failure and are thought to have a major role in the pathophysiology of this disorder. In particular, vasopressin appears to be the major contributor to the development of the hyponatremia observed in patients with heart failure. In patients with AHF, volume overload, and persistent hyponatremia at risk for or already experiencing active cognitive symptoms, therapy with a vasopressin antagonist for short-term improvement in serum sodium concentration may be considered. Currently available vasopressin antagonists are tolvaptan (an oral, selective V2 receptor antagonist) and conivaptan (a V1/V2 receptor antagonist for intravenous use). Although both agents have been approved for the treatment of clinically significant hypervolemic and euvolemic hyponatremia, they have not been shown to improve long-term outcomes in heart failure and are not currently approved for this indication. In patients with heart failure, tolvaptan improves PCWP but not cardiac output.¹⁰⁸ The Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) was an international trial that evaluated more than 4000 patients admitted with AHF and reduced ejection fraction. Tolvaptan added to standard therapy for AHF helped to achieve modest relief of signs and symptoms during hospitalization and modestly reduced body weight without affecting renal function, heart rate, or blood pressure, but postdischarge survival and readmission rate were not affected by chronic postdischarge therapy with this drug.^{109,110} In patients with AHF, the addition of conivaptan to standard therapy increased urine output without a significant relief of signs and symptoms or decrease in body weight.¹¹¹

Calcium Channel Blockers. Calcium channel blockers (CCBs) without significant myocardial depressant effects, such as nicardipine and clevidipine, may be potentially useful in patients with AHF presenting with severe hypertension refractory to other therapies. In a pilot study of 104 patients with hypertensive AHF who exhibited pulmonary congestion, clevidipine rapidly provided significant blood pressure control associated with relief of dyspnea compared with standard of care.

Other Nonpharmacologic Therapies

Ultrafiltration

Peripheral ultrafiltration is an available modality to remove sodium and water in hospitalized patients with heart failure. The theoretical advantage of ultrafiltration is the removal of isotonic fluid, resulting in greater and more reliable salt removal, potentially without the neurohormonal activation seen with diuretics.⁸¹ Potential limitations of ultrafiltration include the need for large bore venous access, systemic anticoagulation, and increased complexity of nursing care related to management of the device. Although theoretically attractive, the appropriate use of ultrafiltration in AHF remains uncertain.

The Ultrafiltration Versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Heart Failure (UNLOAD) trial randomly assigned 200 patients with AHF to undergo venovenous ultrafiltration or receive standard care within 24 hours of initial presentation. Patients receiving ultrafiltration demonstrated a greater reduction in body weight at 48 hours but no improvements in dyspnea and or renal function.¹¹² An intriguing finding was a reduction in postdischarge events at 90 days with ultrafiltration, although the number of events was small. Other recent studies have raised questions about the optimal use of ultrafiltration in heart failure. In an observational study of 63 patients with persistent congestion refractory to hemodynamically guided intensive medical therapy, slow continuous ultrafiltration resulted in improved hemodynamics yet

was associated with high incidence of subsequent transition to renal replacement therapy and high in-hospital mortality.¹¹³ The Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS) randomly assigned 188 patients with AHF, worsened renal function, and persistent congestion to a strategy of stepped pharmacologic care (intravenous diuretics in doses selected by the investigator to maintain urine output of 3 to 5 L per day plus intravenous vasodilators or inotropes if needed to achieve target urine output) or ultrafiltration (fluid removal rate, 200 mL/hour).⁶³ Ultrafiltration resulted in similar weight loss (approximately 12 pounds) but resulted in an increase in creatinine levels, compared with standard care, and was associated with more serious adverse events, especially kidney failure, bleeding complications, and intravenous catheter-related complications. CARRESS enrolled a high-risk population with a composite rate of death or rehospitalization at 60 days of greater than 50%. The ongoing AVOID-HF study (Aquapheresis Versus Intravenous Diuretics and Hospitalizations for Heart Failure) (NCT01474200) will further evaluate the role of ultrafiltration in the management of AHF.

Hypertonic Saline

Administration of hypertonic saline (HSS) (3%), along with high-dose furosemide and sodium and fluid restriction, may be associated with greater diuretic and clinical response.¹¹⁴ The SMAC-HF study randomly assigned 1771 patients hospitalized for AHF to a single-blind strategy of HSS (150 mL 3% NS) plus furosemide 250 mg intravenous bolus twice daily and sodium restriction to 120 mmol/day versus furosemide 250 mg intravenous bolus twice daily and sodium restriction to 80 mmol/day; both groups received a fluid intake of 1000 mL/day.¹¹⁵ After discharge, the HSS group continued with 120 mmol Na/day; the second group continued with 80 mmol Na/day. Shorter length of stay, increased creatinine clearance at discharge, reduced readmission rate, and improved survival were documented for patients in the HSS group. These hypothesis-generating data are intriguing but are limited by the unblinded study design and the potential confounding by postdischarge management. Larger, prospective, blinded trials are needed to further evaluate this therapeutic approach before adoption for clinical practice.

Potential New Therapies

Most of the large clinical trials of new therapies for AHF have yielded negative results in terms of efficacy and/or safety (Table 24-9). A variety of potential explanations for this fact have been proposed, including lack of drug efficacy, patient selection, timing of therapy, and endpoints.¹¹⁶ Nonetheless, in view of the diverse pathophysiology of AHF, it would be unrealistic to expect that a single drug would exert beneficial effects in all, or even most, patients with AHF. There remain areas of significant unmet need in the treatment of AHF, including vasodilators with proven clinical benefits, agents that optimize myocardial performance without significant adverse effects, and agents that improve or protect renal function. A number of interesting compounds are in development or are undergoing clinical evaluation.

Vasodilating Agents

A variety of novel molecules with vasodilator properties are in development as therapeutics for AHF.⁸⁶

Serelaxin

Relaxin was first identified as a major hormone of pregnancy with powerful systemic and renal vascular effects, as well as beneficial effects on cardiac preconditioning and ischemia, inflammation, fibrosis, and apoptosis. Serelaxin (recombinant human relaxin-2) demonstrated encouraging effects in a dose-finding pilot study of 234 patients with AHF.¹¹⁷ The Phase III RELAX-AHF (Efficacy and Safety of Relaxin for the Treatment of Acute Heart Failure) trial enrolled 1161 patients within 16 hours of presentation who had dyspnea, congestion, mild to moderate renal insufficiency, and SBP above 125 mm Hg and randomized them to standard of care with a 48-hour infusion of either serelaxin (30 µg/kg/day) or placebo.¹¹⁸ The trial demonstrated efficacy of serelaxin in improving dyspnea as quantified by the area under the curve (AUC) of the change from baseline dyspnea visual analog scale over 5 days, which was associated with improvements in signs of congestion, decreased in-hospital worsening heart failure, shorter length of stay, and both cardiovascular and all-cause mortality at 180 days. There were no significant changes in the dyspnea

TABLE 24-9 Selected Clinical Trials of Pharmacologic Treatment for Acute Heart Failure

TRIAL	TREATMENT ARMS	POPULATION	RESULTS
VMAC (2002) N = 489	Nesiritide (Nes) (0.01-0.03 µg/kg/min with optional 2 µg/kg bolus; from 24 hr up to 7 days) vs. placebo only during first 3 hr vs. nitroglycerin (NTG) from 24 hr up to 7 days	Dyspnea at rest ≥2 signs of HF within 72 hr CXR with evidence of pulmonary edema	Change in PCWP: at 3 hr*: -5.8 mm Hg Nes, -3.8 mm Hg NTG, -2 mm Hg placebo (P < .001); at 24 hr: -8.2 mm Hg Nes, -6.3 mm Hg NTG (P < .04) Self-evaluation of dyspnea, Likert scale*: at 3 hr: Nes vs. placebo, P = .03; Nes vs. NTG, P = .56; at 24 hr: NTG vs. Nes, P = .13 Self-evaluation of global clinical status: at 3 hr: Nes vs. placebo, P = .07; Nes vs. NTG, P = .33; at 24 hr: NTG vs. Nes, P = .08
OPTIME-HF (2002) N = 951	Milrinone (0.5 µg/kg/min, titratable to 0.75) vs. placebo, for 48-72 hr	Presenting within 48 hr Known systolic HF LVEF ≤40%	Days with CV-related hospitalization or dead in 60 days*: milrinone 12.3 vs. placebo 12.5 (P = .71) Failure of therapy caused by adverse event within 48 hr: milrinone 20.6% vs. placebo 9.2% (P < .001) Excess sustained hypotension (P = .004), new atrial fibrillation/flutter (P < .001), VT/VF (P = .06)
ESCAPE (2005) N = 433	Pulmonary artery catheter (PAC)-guided therapy vs. clinical assessment (CA)-guided therapy	LVEF ≤30% SBP ≤125 mm Hg ≥1 sign and ≥1 symptom of HF 3-mo duration of HF symptoms despite ACE inhibitor and diuretics	Days alive out of hospital during 6 mo*: PAC 133 days vs. CA 135 days (HR, 1.00; 95% CI, 0.82-1.21; P = .99) Greater number of adverse events in PAC group
VERITAS (2007) N = 1435	Tezosentan (Tezo) 5 mg/hr for 30 min, followed by 1 mg/hr for 24-72 hr vs. placebo	Presenting within 24 hr Persistent dyspnea Respiratory rate ≥24 beats/min At least two of the following: elevated BNP/NT-proBNP, clinical pulmonary edema, CXR with evidence of congestion, LV systolic dysfunction	Change in dyspnea AUC, 24 hr*: VERITAS-1: Tezo -562 vs. placebo -550 mm/hr (P = .80); VERITAS-2: Tezo -367 vs. placebo -342 (P = .60) Death or worsening HF at 7 days: VERITAS-1 and -2: Tezo 26.3% vs. placebo 26.4 (P = .95)

TABLE 24-9 Selected Clinical Trials of Pharmacologic Treatment for Acute Heart Failure—cont'd

TRIAL	TREATMENT ARMS	POPULATION	RESULTS
SURVIVE (2007) N = 1327	Levosimendan (Levo) (loading dose 12 µg/kg, followed by 0.1-0.2 µg/kg/min; for 24 hr) vs. dobutamine (Dob) (5 µg/kg/min, titratable up to 40 µg/kg/min; for at least 24 hr)	LVEF ≤30% Requiring IV inotropic support At least one of following: dyspnea at rest, oliguria, PCWP ≥18 mm Hg or CI ≤2.2 L/min/m ²	All-cause mortality, 180 days*: Levo 26% vs. Dob 28% (HR, 0.91; 95% CI, 0.74-1.13; P = .40) Change in BNP from baseline to 24 hr: Levo -631 vs. Dob -397, P < .001 No change in dyspnea at 24 hr, days alive out of hospital at 180 days, all-cause mortality at 31 days, CV mortality at 180 days
EVEREST (2007) N = 4133	Tolvaptan (Tol) (30 mg PO once daily) vs. placebo, for at least 60 days	Randomized within 48 hr NYHA class III-IV symptoms LVEF ≤40% Signs of volume expansion	Composite of changes in global clinical status and body weight, 7 days*: P < .001, for Tol superiority; no difference in clinical status; change in body weight, 1 day: Tol -1.76 kg vs. placebo -0.97; P < .001 All-cause mortality*: Tol 25.9% vs. placebo 26.3% (HR, 0.98; 95% CI, 0.87-1.11; superiority P = .68; noninferiority P < .001) CV death or HF hospitalization*: Tol 42.0% vs. placebo 40.2% (HR, 1.04; 95% CI, 0.95-1.14; superiority: P = .55)
UNLOAD (2007) N = 200	Ultrafiltration (UF), (with fluid removal titrated by investigator up to 500 mL/hr) vs. diuretic (titrated by investigator, at least twice-daily oral dose), for 48 hr	Randomized within 24 hr ≥2 signs of congestion	Weight loss, 48 hr*: UF -5.0 kg vs. diuretics -3.1, P = .001 Dyspnea score, 48 hr*: UF 6.4 vs. diuretics 6.1; P = .35 HF rehospitalization, 90 days: UF 0.22 vs. diuretics 0.46, P = .022; days rehospitalized: UF 1.4 days vs. diuretics 3.8; P = .022; unscheduled HF visits: UF 21% of pts. vs. diuretics 44%, P = .009
3CPO (2008) N = 1069	Noninvasive positive-pressure ventilation (NIPPV) vs. continuous positive airway pressure (CPAP) vs. oxygen therapy (O ₂)	Clinical diagnosis of cardiogenic pulmonary edema CXR: evidence of pulmonary edema Respiratory rate >20 beats/min Arterial pH <7.35	All-cause mortality, 7 days*: NIPPV + CPAP 9.5% vs. O ₂ 9.8% (OR, 0.97; 95% CI, 0.63-1.48; P = .87) Composite death or intubation, 7 days*: NIPPV + CPAP 11.1% vs. O ₂ 11.7% (OR, 0.94; 95% CI, 0.59-1.51; P = .81) NIPPV + CPAP better than O ₂ : change in arterial pH 1 hr (P < .001); dyspnea score 1 hr (P = .008)
DAD-HF (2010) N = 60	Dopamine 5 µg/kg/min plus low-dose furosemide (5 mg/hr continuous infusion) vs. high-dose furosemide (20 mg/hr continuous infusion)	Hospitalized for ADHF with evidence of volume overload and eGFR ≥30 mL/min/1.73 m ²	Serum creatinine increase >0.3 mg/dL within 24 hr*: 6.7% low-dose dopamine/low-dose furosemide vs. 30% high-dose furosemide; P = .042 >20% decrease in eGFR within 24 hr*: 10% low-dose dopamine/low-dose furosemide vs. 33.3% high-dose furosemide; P = .057
PROTECT (2010) N = 2033	Rolofylline 30 mg vs. placebo for up to 3 days	Randomized within 24 hr Persistent dyspnea at rest or with minimal activity, estimated CrCl 20-80 mL/min, BNP ≥500 pg/mL or NT-proBNP ≥2000 pg/mL, IV loop diuretic therapy	Clinical composite*: OR for rolofylline 0.92; 95% CI, 0.78-1.09; P = .35
DOSE (2011) N = 308	Low- vs. high-dose furosemide Continuous infusion vs. intermittent intravenous bolus 1:1:1:1 2×2 factorial design	Randomized within 24 hr, ≥1 sign and ≥1 symptom of HF, history of chronic HF treated with furosemide 80-240 mg/day (or equivalent) for at least 1 mo	Global assessment of symptoms*: 4236 ± 1440 AUC bolus vs. 4373 ± 1404 AUC continuous infusion, P = .47; 4171 ± 1436 AUC low dose vs. 4430 ± 1401 AUC high dose, P = .06 Mean change in serum creatinine*: 0.05 mg/dL bolus vs. 0.07 mg/dL continuous infusion, P = .45; 0.04 mg/dL low dose vs. 0.08 mg/dL high dose, P = .21
ASCEND-HF (2011) N = 7141	Nesiritide (Nes) 0.01 µg/kg/min with optional 2 µg/kg bolus (from 24 hr up to 7 days) vs. placebo	Hospitalized for ADHF, dyspnea at rest or with minimal activity, ≥1 sign and ≥1 objective measure of ADHF, randomized within 24 hr of first IV treatment for ADHF	Self-reported dyspnea moderately or markedly better: at 6 hr: 42.1% placebo vs. 44.5% Nes, P = .03; at 24 hr: 66.1% placebo vs. 68.2% Nes, P = .007 Death or rehospitalization for HF at 30 days: 10.1% placebo vs. 9.4% Nes (HR, 0.93; 95% CI, 0.8-1.08; P = .31)
CARRESS-HF (2012) N = 188	Ultrafiltration (UF) vs. stepped pharmacologic care (Pharm)	Develop cardiorenal syndrome before (within 6 weeks) or after (within 7 days from admission) hospitalization	Change in creatinine level: UF +0.23 mg/dL vs. Pharm -0.04 ± 0.53 mg/dL in Pharm group vs. UF group, P = .003 Weight loss: 5.5 ± 5.1 kg [12.1 ± 11.3 lb] in Pharm group vs. 5.7 ± 3.9 kg [12.6 ± 8.5 lb] in UF group; P = .58 Serious adverse events: 72% in UF group vs. 57% in Pharm group; P = .03

Continued

TABLE 24-9 Selected Clinical Trials of Pharmacologic Treatment for Acute Heart Failure—cont'd

TRIAL	TREATMENT ARMS	POPULATION	RESULTS
RELAX-AHF (2013) N = 1161	Serelaxin (Ser) 30 µg/kg/day vs. placebo for 48 hr	Patients with dyspnea at rest or on minimal exertion, congestion on CXR, BNP ≥350 ng/L (or NT-proBNP ≥1400 ng/L), eGFR 30-75 mL/min/1.73 m ² , and SBP >125 mm Hg	Change in dyspnea by VAS AUC to day 5*: 19% improvement by Ser compared with placebo by VAS AUC (448 mm/hr, 95% CI, 120-775), P = .007 Proportion of patients with moderately or markedly improved dyspnea by Likert scale at all 3 early timepoints (6, 12, 24 hr*): Ser 27% vs. placebo 26%; P = .70 Days alive out of hospital up to day 60: Ser 48.3 vs. placebo 47.7, P = .37 180-day mortality: placebo 65 deaths vs. Ser 42; (HR, 0.63; 95% CI, 0.43-0.93; P = .02)
REVIVE-2 (2013) N = 600	Levosimendan (Levo) (loading dose 12 µg/kg, followed by 0.1-0.2 µg/kg/min, for 24 hr) vs. placebo	Dyspneic at rest LVEF ≤35%	Clinical composite endpoint, 5 days*: Levo superior, P = .015 More frequent hypotension and cardiac arrhythmias during infusion period; numerically higher risk of death, 90 days (REVIVE-1, -2: Levo, 49 deaths/350 pts. vs. placebo, 40/350, P = .29)

*Primary endpoint.

†Did not meet prespecified U.S. regulatory requirement of significance.

AUC = area under the curve; CrCl = creatinine clearance; CV = cardiovascular; CXR = chest x-ray [examination/film]; HF = heart failure; HR = hazard ratio; IV = intravenous; NYHA = New York Heart Association; OR = odds ratio; VT/VF = ventricular tachycardia/ventricular fibrillation.

score as assessed by the seven-level Likert scale over the first 24 hours nor in any endpoint related to heart failure rehospitalizations. Serelaxin treatment also was associated with improved levels of biomarkers of end-organ damage or dysfunction, including cardiac, renal, and hepatic markers.¹¹⁹ No serious adverse events of hypotension or other safety signals occurred in the serelaxin-treated patients. Additional studies are being conducted to determine the future role of serelaxin in the treatment of patients with AHF.

Other Natriuretic Peptides

Multiple different natriuretic peptides continue to be developed and investigated for the treatment of AHF, including naturally occurring and alternatively spliced¹²⁰ peptides and chimeric designer peptides. *Urodilatin*, a modified version of pro-atrial natriuretic peptide (pro-ANP), is a 32-amino-acid hormone, synthesized and secreted from the distal tubules of the kidney that regulates renal sodium absorption and water homeostasis via binding to NPR1 receptors and increasing intracellular cGMP levels. *Ularitide*, a synthetically produced urodilatin, has demonstrated beneficial effects on hemodynamics and symptom relief in two studies of patients with AHF.^{121,122} The TRUE-AHF trial (NCT01661634) is currently enrolling patients with symptomatic AHF, with a target sample size of 2116, randomly assigned to receive a 48-hour infusion of either ularitide (15 ng/kg/min) or placebo. Chimeric natriuretic peptides are molecularly engineered to optimize the beneficial aspects of different natriuretic peptides into a single molecule, while attempting to minimize any potential negative side effects. CD-NP combines the beneficial aspects of C-type natriuretic peptide (CNP) with dendroaspis natriuretic peptide (DNP).¹²³ The CNP moiety is primarily a venodilator, whereas DNP has significant natriuretic effects. *Cenderitide* (CD-NP) ideally combines the lack of unwanted arterial vasodilation of CNP

with the positive natriuretic effects of DNP. Early clinical studies demonstrated encouraging effects, although hypotension complicated some doses. Preliminary studies in heart failure are ongoing.

Neurohormonal Antagonists

Direct renin inhibitors (DRIs) block the first enzymatic step in the RAAS cascade, leading to a profound suppression of this neurohormonal system (see Chapters 22 and 25). Given the role of RAAS in the pathogenesis of heart failure and its complications, as well as the improved survival associated with its inhibition, it is hypothesized that further blockade of this system may confer additional survival benefits. In a study of 16 patients with AHF, *aliskiren*, the first oral DRI on the market and currently approved for the treatment of hypertension, reduced systemic vascular resistance (SVR) with trends to increasing cardiac index, but had no effect on pulmonary capillary wedge pressure.¹²⁴

The ASTRONAUT trial is evaluating the 6-month efficacy and safety of chronic oral aliskiren therapy in addition to standard therapy, on post discharge mortality and rehospitalization rates when initiated early after AHF hospital admission and before discharge in approximately 1700 patients hospitalized for AHF with ejection fraction less than 40%.¹²⁵ *Endothelin receptor antagonists* block the actions of endothelin-1 (ET-1), the most powerful endogenous vasoconstrictor that is produced by the vascular endothelial cells. It exerts its effects by binding to two receptors, ET_A and ET_B, located on the vascular smooth muscle cells, resulting in significant systemic arterial vasoconstriction. *Tezosentan*, a nonselective ET_{A/B} antagonist, has been shown to improve hemodynamics in patients with AHF.

The Value of Endothelin Receptor Inhibition with Tezosentan in Acute Heart Failure Study (VERITAS) studied more than 1400 patients hospitalized with AHF in a large international trial. The addition of intravenous tezosentan to standard therapy did not alleviate

symptoms or decrease worsening heart failure or mortality rate at 7 days after initiation of treatment.¹²⁶ Other novel approaches to neurohormonal antagonism in AHF, such as novel *angiotensin II type 1 receptor beta-arrestin-biased ligands*,^{127,128} which agonize favorable (beta-arrestin-mediated) pathways while simultaneously antagonizing angiotensin II signaling, are in development.

Soluble Guanylate Cyclase Activators

Cinaciguat is the first compound in a new class of vasodilators. The mechanism of action of these compounds is similar to that of organic nitrates (and their end product nitric oxide [NO]), because both classes of drugs activate the soluble form of guanylate cyclase (sGC) in smooth muscle cells, thereby leading to the synthesis of cGMP and subsequent vasodilation. *Cinaciguat* has been shown to improve hemodynamics in patients with AHF; however, at high doses, it has been associated with significant hypotension, which resulted in the termination of some recent clinical studies.¹²⁹⁻¹³¹

Inotropic Agents

Cardiac Myosin Activators

Cardiac myosin activators represent a new mechanistic class of agents designed to increase myocardial contractility. These agents increase the transition rate from the weakly bound to the strongly bound state necessary for initiation of a force-generating power stroke. Unlike current inotropes, they increase the systolic ejection time without altering the rate of LV pressure development, resulting in increased stroke volume and cardiac output without increases in intracellular cAMP or calcium.¹³² *Omecamtiv mecarbil* is the first agent of this class to undergo testing in humans. In both healthy volunteers¹³³ and patients with chronic stable heart failure with reduced ejection fraction,¹³⁴ administration of *omecamtiv mecarbil* produced dose-dependent increases in systolic ejection time, fractional shortening, stroke volume, and ejection fraction and was well tolerated over a broad range of plasma concentrations. A phase IIb study of *omecamtiv mecarbil* in patients with AHF is under way (ATOMIC-AHF [NCT01300013]).

Istaroxime

Istaroxime, the prototype of a new class of drugs, exerts its actions on the myocyte in two ways: (1) through stimulation of the membrane-bound sodium-potassium adenosine triphosphatase (Na⁺, K⁺-ATPase) and (2) by enhancing the activity of the sarcoendoplasmic reticulum Ca²⁺-ATPase type 2a (SERCA-2a). These distinct mechanisms result in, respectively, increased cytosolic calcium accumulation during systole, with positive inotropic effects, and rapid sequestration of cytosolic calcium into the sarcoplasmic reticulum during diastole, leading to an enhanced lusitropic effect.¹³⁵ The HORIZON-HF study evaluated 120 patients admitted with AHF and decreased ejection fraction. The addition of *istaroxime* to standard therapy lowered PCWP and heart rate and increased SBP. The higher infusion dose increased cardiac index and reduced LV end-diastolic volume. No changes were observed in neurohormones, renal function, or troponin I levels during the short 6-hour infusion.^{136,137}

Other Inotropic Agents

Stresscopin, or urocortin 2, is a member of the urocortin family, a recently discovered group of peptide hormones of the corticotropin-releasing factor (CRF) family. They bind with strong affinity to the corticotropin-releasing hormone receptor type 2 (CRH-R2), which is highly expressed in the myocardium and in the vascular endothelium. Urocortins exhibit potent inotropic and lusitropic effects on rat and sheep hearts and activate a group of myocyte protective pathways collectively known as “reperfusion injury salvage kinase” (RISK). Studies in patients with heart failure showed that brief intravenous infusions of *stresscopin* produced dose-related increases in cardiac output, heart rate, and LV ejection fraction while decreasing systemic vascular resistance.¹³⁸

Renoprotective Agents

Therapeutics to prevent or treat acute kidney injury and maintain or improve renal function in the setting of AHF are an important unmet

need. *Adenosine A₁ receptor antagonists* have been developed to increase renal blood flow and enhance diuresis without activating the tubuloglomerular feedback. *Rolofylline* is a highly selective adenosine A₁ receptor antagonist that has been studied in patients with heart failure. Despite the positive trends seen in the PROTECT-Pilot study,¹³⁹ the Phase III PROTECT trial failed to show any clinical benefit, including renal protection,¹⁴⁰ and use of *rolofylline* was associated with more seizure and stroke events when compared with placebo.¹⁴¹ In view of these results, it is doubtful that these agents will undergo further evaluation in AHF.

FUTURE PERSPECTIVES

AHF remains one of the most challenging cardiovascular problems, with unacceptably high postdischarge rehospitalization and mortality rates. The development of new therapies has been a persistent challenge over recent decades, and most patients are still treated primarily with intravenous loop diuretics. Current management consists primarily of treating the manifestations of the syndrome rather than central pathophysiologic derangements. Improvement in understanding of underlying pathophysiology and better targeting of treatments to specific patient groups most likely to benefit will potentially provide greater success in developing efficacious new therapies for AHF. In view of the heterogeneity of the AHF-afflicted population, it is unlikely that a “one therapy fits all” approach will lead to an improvement in outcomes. At the same time that new therapies are sought, continued efforts to improve and standardize the use of “best practices” in terms of process of care, transitions of care, and post-discharge follow-up, will potentially allow better use of currently available therapies to improve outcomes from this highly morbid condition.

GUIDELINES

The Hospitalized Patient with Heart Failure

G. Michael Felker and John R. Teerlink

Here we review the most recent guidelines for management of the patient hospitalized with acute heart failure (AHF), those released by the ACC/AHA in 2013 (**Table 24G-1**). These new guidelines expand the 2009 ACC/AHA guidelines with several new class I recommendations. These include the use of BNP or NT-proBNP and/or troponin for establishing prognosis in AHF, more detailed recommendations about the appropriate use of diuretics, and more comprehensive and detailed recommendations about transition of care

from the hospital to the ambulatory setting. Although the 2013 ACC/AHA guidelines are in general agreement with the 2012 ESC Heart Failure guidelines in most areas, some distinct differences in emphasis can be delineated. Reflecting this divergent emphasis is use of the term “hospitalized patient with HF” in the ACC/AHA guidelines versus “acute heart failure” in the ESC guidelines. In addition, the ESC guidelines focus in significantly more detail on specific issues of acute therapy and distinguish particular sets of more detailed recommendations in patients with AHF based on phenotype (e.g., AHF with pulmonary congestion without shock, AHF with ACS, ACS with atrial fibrillation). Use of parenteral vasodilators receives a stronger recommendation (IIA) in the ESC guidelines than in the new ACC/AHA guidelines (IIB). By contrast, the new ACC/AHA guidelines provide more detailed recommendations regarding transitions and follow-up after discharge from the hospital.

TABLE 24G-1 ACC/AHA Recommendations for the Patient Hospitalized with Acute Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
Biomarkers		
I	Measurement of BNP or NT-proBNP is useful to support clinical judgment for the diagnosis of acutely decompensated HF, especially in patients in whom the diagnosis is uncertain.	A
I	Measurement of BNP or NT-proBNP and/or cardiac troponin is useful for establishing prognosis or disease severity in acutely decompensated HF.	A
IIb	The usefulness of BNP- or NT-proBNP-guided therapy for acutely decompensated HF is not well established.	C
IIb	Measurement of other clinically available tests such as biomarkers of myocardial injury or fibrosis may be considered for additive risk stratification in patients with acutely decompensated HF.	A
Precipitating Causes of AHF		
I	ACS precipitating acute HF decompensation should be promptly identified by ECG and serum biomarkers, including cardiac troponin testing, and treated optimally as appropriate to the overall condition and prognosis of the patient.	C
I	Common precipitating factors for acute HF should be considered during initial evaluation, as recognition of these conditions is critical to guide appropriate therapy.	C
Invasive Evaluation		
I	Invasive hemodynamic monitoring with a pulmonary artery catheter should be performed to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment.	C
IIA	Invasive hemodynamic monitoring can be useful for carefully selected patients with acute HF who have persistent symptoms despite empirical adjustment of standard therapies and: a. Whose fluid status, perfusion, or systemic or pulmonary vascular resistance is uncertain; b. Whose systolic pressure remains low, or is associated with symptoms, despite initial therapy; c. Whose renal function is worsening with therapy; d. Who require parenteral vasoactive agents; or e. Who may need consideration for MCS or transplantation	C
III	Routine use of invasive hemodynamic monitoring is not recommended in normotensive patients with acute decompensated HF and congestion with symptomatic response to diuretics and vasodilators.	B
Maintenance of Guideline-Directed Medical Therapy (GDMT) During Hospitalization		
I	In patients with HFrEF experiencing a symptomatic exacerbation of HF requiring hospitalization during chronic maintenance treatment with GDMT, it is recommended that GDMT be continued in the absence of hemodynamic instability or contraindications.	B
I	Initiation of beta blocker therapy is recommended after optimization of volume status and successful discontinuation of intravenous diuretics, vasodilators, and inotropic agents. Beta blocker therapy should be initiated at a low dose and only in stable patients. Caution should be used in initiating beta blockers in patients who have required inotropes during their hospital course.	B
Diuretics		
I	Patients with HF admitted with evidence of significant fluid overload should be promptly treated with intravenous loop diuretics to reduce morbidity.	B
I	If patients are already receiving loop diuretic therapy, the initial intravenous dose should equal or exceed their chronic oral daily dose and should be given as either intermittent boluses or continuous infusion. Urine output and signs and symptoms of congestion should be serially assessed, and the diuretic dose should be adjusted accordingly to relieve symptoms, reduce volume excess, and avoid hypotension.	B
I	The effect of HF treatment should be monitored with careful measurement of fluid intake and output, vital signs, body weight that is determined at the same time each day, and clinical signs and symptoms of systemic perfusion and congestion. Daily serum electrolytes, urea nitrogen, and creatinine concentrations should be measured during the use of intravenous diuretics or active titration of HF medications.	C
IIA	When diuresis is inadequate to relieve symptoms, it is reasonable to intensify the diuretic regimen using: a. Higher doses of intravenous loop diuretics or b. Addition of a second (e.g., thiazide) diuretic	B
IIb	Low-dose dopamine infusion may be considered in addition to loop diuretic therapy to improve diuresis and better preserve renal function and renal blood flow.	B
Venous Thromboembolism Prophylaxis		
I	A patient admitted to the hospital with decompensated HF should receive venous thromboembolism prophylaxis with an anticoagulant medication if the risk-benefit ratio is favorable.	B

**TABLE 24G-1 ACC/AHA Recommendations for the Patient Hospitalized with Acute Heart Failure—cont'd**

CLASS	INDICATION	LEVEL OF EVIDENCE
Ultrafiltration		
IIB	Ultrafiltration may be considered for patients with obvious volume overload to alleviate congestive symptoms and fluid weight.	B
IIB	Ultrafiltration may be considered for patients with refractory congestion not responding to medical therapy.	C
Parenteral Therapy		
IIB	If symptomatic hypotension is absent, intravenous nitroglycerin, nitroprusside, or nesiritide may be considered an adjuvant to diuretic therapy for relief of dyspnea in patients admitted with acutely decompensated HF.	A
Inotropic Support and Mechanical Circulatory Support (MCS)		
I	Until definitive therapy (e.g., coronary revascularization, MCS, heart transplantation) or resolution of the acute precipitating problem, patients with cardiogenic shock should receive temporary intravenous inotropic support to maintain systemic perfusion and preserve end-organ performance.	C
IIA	Nondurable MCS is reasonable as a “bridge to recovery” or “bridge to decision” for carefully selected patients with HF and acute profound disease.	B
IIB	Short-term, continuous intravenous inotropic support may be reasonable in those hospitalized patients with documented severe systolic dysfunction who present with low blood pressure and significantly depressed cardiac output, to maintain systemic perfusion and preserve end-organ performance.	B
III	Use of parenteral inotropic agents in hospitalized patients without documented severe systolic dysfunction, low blood pressure, or impaired perfusion who present with evidence of significantly depressed cardiac output, with or without congestion, is potentially harmful.	B
Arginine Vasopressin Antagonists		
IIB	In patients hospitalized with volume overload, including HF, who have persistent severe hyponatremia and have or are at risk for having active cognitive symptoms despite water restriction and maximization of GDMT, vasopressin antagonists may be considered in the short term to improve serum sodium concentration in hypervolemic, hyponatremic states with either a V2 receptor–selective or a nonselective vasopressin antagonist.	B
Transitions of Care		
I	The use of performance improvement systems and/or evidence-based systems of care is recommended in the hospital and early postdischarge outpatient setting to identify appropriate HF patients for GDMT, provide clinicians with useful reminders to advance GDMT, and assess the clinical response.	B
I	Throughout the hospitalization as appropriate, before hospital discharge, at the first postdischarge visit, and in subsequent follow-up visits, the following should be addressed: a. Initiation of GDMT if not done or contraindicated b. Causes of HF, barriers to care, and limitations in support c. Assessment of volume status and blood pressure with adjustment of HF therapy d. Optimization of chronic oral HF therapy e. Renal function and electrolytes f. Management of comorbid conditions g. HF education, self-care, emergency plans, and adherence h. Palliative or hospice care	B
I	Multidisciplinary HF disease management programs are recommended for patients at high risk for hospital readmission, to facilitate the implementation of GDMT, to address different barriers to behavioral change, and to reduce the risk of subsequent rehospitalization for HF.	B
IIA	Scheduling an early follow-up visit (within 7 to 14 days) and early telephone follow-up (within 3 days) of hospital discharge is reasonable.	B
IIA	Use of clinical risk prediction tools and/or biomarkers to identify patients at higher risk for postdischarge clinical events is reasonable.	B

EPIDEMIOLOGY

The worldwide prevalence and incidence rates of heart failure (HF) are approaching epidemic proportions, as evidenced by the relentless increase in the number of HF-related hospitalizations, the growing number of HF-attributable deaths, and the spiraling costs associated with the care of patients with HF. Worldwide, HF affects nearly 23 million people. In the United States, the most recent epidemiologic data suggest that 5.1 million Americans 20 years of age and older have HF, and it is estimated that by 2030, the prevalence will increase 25% from current estimates.¹ Estimates of the prevalence of symptomatic HF in the general European population are similar to that in the United States, ranging from 0.4 to 2%.² The prevalence of HF rises exponentially with age, and the condition affects 4% to 8% of people older than 65 years of age (**Fig. 25-1A**). Although the relative incidence of HF is lower in women than men for all age groups (**Fig. 25-1B**), women constitute at least half of the cases of HF because of their longer life expectancy, and the overall prevalence of HF is greater in women than in men 80 years of age and older.¹ In the ARIC (Atherosclerosis Risk in Communities) study, funded by the National Institutes of Health (NIH), the age-adjusted incidence of HF was greatest in black men, followed by black women, white men, and white women. The higher incidence of HF in blacks was attributed to the greater levels of atherosclerosis risk factors in this population.³ Similar findings were observed in the NIH-funded MESA (Multi-Ethnic Study of Atherosclerosis) study, which showed that blacks had the highest risk for development of HF, followed by Hispanic, white, and Chinese Americans¹ (**Fig. 25-2**). In North America and Europe, the lifetime risk of developing HF is approximately 1 in 5 for a 40-year-old. The overall prevalence of HF is thought to be increasing, in part because current therapies of cardiac disorders, such as myocardial infarction (MI), valvular heart disease, and arrhythmias, are allowing patients to survive longer. Very little is known with respect to the prevalence or risk of developing HF in emerging nations because of the lack of population-based studies in those countries.⁴ Although HF was once thought to arise primarily

in the setting of a depressed left ventricular ejection fraction (LVEF), epidemiologic studies have shown that approximately one half of patients who develop HF have a normal or preserved EF (EF > 50%). Accordingly, patients with HF are now broadly categorized as having either (1) HF with a reduced or depressed EF (HFrEF) of 35% or less, also referred to as *systolic failure*, or (2) HF with a preserved EF (HFpEF) at 50% or greater, also referred to as *diastolic failure*. HF in patients with an EF in the range 35% to 50% represents a “gray zone”; such patients are likely to have at least mild systolic dysfunction. The epidemiology of HFpEF is discussed in **Chapter 27**.

Risk factors for the development of HF in men and women include coronary artery disease (CAD), hypertension, diabetes, obesity, and smoking.⁵ Of importance, the burden of all risk factors among HF cases has increased over time, with significant increases for hypertension, obesity, and smoking. However, the relative contribution of risk factors to the development of HF remains controversial, with some population-based studies suggesting that hypertension has the highest attributable risk and others suggesting that CAD has the greatest impact on the development of HF. In a more recent population-based case-control study, the population-attributable risk for developing HF was greatest for CAD, followed by diabetes, obesity, hypertension, and smoking (**Table 25-1**). Of interest, sex-based differences in the cause of HF also were noted, with hypertension playing the greatest role in women and coronary disease in men. Although obesity is a risk factor for the development of HF, obese patients with HF seem to enjoy a more favorable clinical prognosis. The association between obesity, a traditional cardiovascular risk factor, and improved clinical outcomes in patients with HF (i.e., reverse epidemiology) has been called the “obesity paradox.”

ETIOLOGY

As shown in **Table 25-2**, any condition that leads to an alteration in left ventricular (LV) structure or function can predispose the patient

to the development of HF. Although the etiology of HF in patients with a preserved EF differs from that in patients with depressed EF (see Chapter 27), considerable overlap between the etiologic mechanisms for these two conditions is recognized. In industrialized countries, CAD is the predominant cause in men and women and is

responsible for 60% to 75% of cases of HF. Hypertension contributes to the development of HF in a significant number of patients, including most patients with CAD. Both CAD and hypertension interact to augment the risk of HF. Rheumatic heart disease remains a major cause of HF in Africa and Asia, especially in the young. Hypertension is an important cause of HF in the African and African American populations. Chagas' disease is still a major cause of HF in South America.⁶ As developing nations undergo socioeconomic development, the epidemiology of HF is becoming similar to that of Western Europe and North America, with CAD emerging as the single most common cause of HF.

In 20% to 30% of the cases of HFrEF, the exact etiologic basis is not known. These patients are referred to as having nonischemic, dilated, or idiopathic cardiomyopathy if the cause is unknown (see Chapter 65). Previous viral infection (Chapter 67) or toxin exposure (e.g., with excess alcohol consumption [Chapter 68] or use of chemotherapeutic agents [Chapter 69]) also may lead to a dilated cardiomyopathy. Although excessive alcohol consumption can promote cardiomyopathy, alcohol consumption per se is not associated with increased risk for HF and may protect against the development of HF when consumed in moderation.⁷ It also is becoming increasingly clear that a large number of cases of dilated cardiomyopathy are secondary to specific genetic defects, most notably those in the cytoskeleton (see Chapter 65). Most of the forms of familial dilated cardiomyopathy are inherited in autosomal dominant fashion. Mutations of genes encoding cytoskeletal proteins (desmin, cardiac myosin, vinculin) and nuclear membrane proteins (lamin) have been identified thus far. Dilated cardiomyopathy also is associated with

Duchenne's, Becker's, and limb-girdle muscular dystrophies (see Chapter 87). Conditions that lead to high cardiac output (e.g., arteriovenous fistula, anemia) seldom are responsible for the development of HF in a normal heart. In the presence of underlying structural heart disease, however, such conditions often lead to overt congestive failure.

PROGNOSIS

Although several recent reports have suggested that the mortality for patients with HF is subsiding, the overall mortality rate remains higher than for many cancers, including those involving the bladder, breast, uterus, and prostate. In the Framingham Heart Study, the median survival was 1.7 years for men and 3.2 years for women, with only 25% of men and 38% of women surviving 5 years. European studies have confirmed a similar poor long-term prognosis² (Fig. 25-3). More recent data from the Framingham Heart Study have examined long-term trends in the survival of patients with HF and shown improved survival in both men and women, with an overall decline in mortality of approximately 12 % per decade from 1950 to 1999. Moreover, recent reports from Scotland, Sweden, and the United Kingdom suggested that survival rates after hospital discharge also may be improving.² Of note, the mortality for HF in epidemiologic studies is substantially higher than that reported in clinical HF trials involving drug and/or device therapies, in which the mortality figures often are deceptively low, because the patients enrolled in trials are younger, are more stable clinically, and tend to be followed more closely clinically.

FIGURE 25-3 Survival in patients with HF versus cancer: Five-year survival rates after a first admission to any Scottish hospital in 1991 for HF, MI, and the four most common sites of cancer specific to men and women. (Modified from Stewart S, MacIntyre K, Hole DJ, et al: More 'malignant' than cancer? Five-year survival following a first admission for heart failure. *Eur J Heart Fail* 3:315, 2001.)

The role of sex in HF prognosis remains a controversial issue with respect to HF outcomes. Nonetheless, the aggregate data suggest that women with HF have a better overall prognosis than do men.¹ However, women appear to have a greater degree of functional incapacity for the same degree of LV dysfunction and also have higher prevalence of HF with a normal EF (see Chapter 27). Controversy also has arisen regarding the impact of race on outcome, with higher mortality rates being reported in blacks in some but not all studies. In the United States, HF affects approximately 3% of blacks, whereas in the general population worldwide, the prevalence is approximately 2%.⁸ Blacks with HF present at an earlier age and have more advanced LV dysfunction and a worse New York Heart Association (NYHA) functional class at the time of diagnosis. Although the reasons for these differences are not known, as noted previously, differences in HF etiology might explain some of these observations. Additional socioeconomic factors also may potentially influence outcomes in black patients, such as geographic location and access to health care. Age is one of the strongest and most consistent predictors of adverse outcome in HF (see later under "Special Populations").⁹

Many other factors have been associated with increased mortality in patients with HF (Table 25-3). Most of the factors listed as outcome predictors have survived, at least, univariate analysis, with many standing out independently when multifactorial analysis techniques are used. Nonetheless, it is extraordinarily difficult to determine which prognostic variable is most important to predict individual patient outcome either in clinical trials or, more important, during the day-to-day management of an individual patient. To this end, several multivariate models for predicting the HF prognosis have been developed and validated. One such model is the Seattle Heart Failure Model, derived by retrospectively investigating predictors of survival among patients with HF in clinical trials. The Seattle Heart Failure Model provides an accurate estimate of 1-, 2-, and 3-year survival rates with the use of easily obtained clinical, pharmacologic, device, and laboratory characteristics and is accessible free of charge to all health care providers as an interactive web-based program (<http://depts.washington.edu/shfm>).

Biomarkers and Prognosis

The observation that the renin-angiotensin-aldosterone, adrenergic, and inflammatory systems are activated in HF (see Chapter 22) has prompted examination of the relationships between a variety of biochemical measurements and clinical outcomes (see Table 25-3).

**TABLE 25-3 Prognostic Variables in Patients with Heart Failure**

Demographics	Exercise Testing
Sex	Metabolic assessment
Race	Blood pressure response
Age	Heart rate response
Heart Failure Etiology	6-minute walk
CAD	Peak VO ₂
IDCM	Anaerobic threshold
Valvular heart disease	VE/VCO ₂
Myocarditis	Oxygen uptake slope
Hypertrophy	Metabolic
Alcohol	Serum sodium
Anthracyclines	Thyroid dysfunction
Amyloidosis	Anemia
Hemochromatosis	Acidosis/alkalosis
Genetic factors	Chest X-ray
Comorbid Conditions	Congestion
Diabetes	Cardiothoracic ratio
Systemic hypertension	ECG
Pulmonary hypertension	Rhythm (atrial fibrillation or arrhythmias)
Sleep apnea	Voltage
Obesity/cachexia (body mass)	QRS width
Renal insufficiency	QT interval
Hepatic abnormalities	Signal-averaged ECG (T wave alternans)
COPD	HR variability
Clinical Assessment	Biomarkers
NYHA functional class (symptoms)	NE, PRA, AVP, aldosterone
Syncope	ANP, BNP, NT-proBNP, endothelin
Angina pectoris	TNF, sTNFR 1, sTNFR 2, galectin-3, pentraxin-3, SST2
Systolic vs. diastolic dysfunction	Cardiac troponins, hematocrit
Hemodynamics	Endomyocardial Biopsy
LVEF	Inflammatory states
RVEF	Degree of fibrosis
PAP	Degree of cellular disarray
PCWP	Infiltrative processes
CI	
PAP-PCWP	
Exercise hemodynamics	

CI = cardiac width; COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; ECG = electrocardiogram; ESR = erythrocyte sedimentation rate; IDCM = idiopathic dilated cardiomyopathy; IL = interleukin; NE = norepinephrine; PAP = pulmonary artery pressure; PAP-PCWP—gradient across lung; PRA = plasma renin activity; PCWP = pulmonary capillary wedge pressure; RVEF = right ventricular ejection fraction; SST2 = somatostatin receptor 2; sTNFR = soluble TNF receptor. Modified from Young JB: *The prognosis of heart failure*. In Mann DL (ed): *Heart Failure: A Companion to Braunwald's Heart Disease*. Philadelphia, Saunders, 2004, pp 489-506.

Strong inverse correlations have been reported between survival and plasma levels of norepinephrine, renin, arginine vasopressin (AVP), aldosterone, atrial and brain natriuretic peptides (ANP and BNP) and N-terminal pro-B-type natriuretic peptide (NT-proBNP), endothelin-1, and inflammatory markers such as tumor necrosis factor (TNF), soluble TNF receptors, C-reactive protein, galectin-3, pentraxin-3, and soluble ST2 (see also Chapter 23). Markers of oxidative stress, such as oxidized low-density lipoprotein and serum uric acid, also have been associated with worsening clinical status and impaired survival in patients with chronic HF. Cardiac troponins T and I, sensitive markers of myocyte damage, may be elevated in patients with nonischemic HF and predict adverse cardiac outcomes. The association between a low hemoglobin or hematocrit and adverse HF outcomes also has long been recognized and recently has garnered considerable attention after several reports illustrated the independent prognostic value of anemia in patients with HF with either reduced or normal ejection fraction.¹⁰

Published estimates of the prevalence of anemia (defined as a hemoglobin concentration less than 13 g/dL in men and less than 12 g/dL in women) in patients with HF vary widely, ranging from 4% to 50%, depending on the population studied and the definition of anemia that is used. In general, anemia is associated with more HF symptoms, worse NYHA functional status, greater risk of HF hospitalization, and reduced survival.¹⁰ Unclear, however, is whether anemia is a cause of decreased survival or simply a marker of more advanced disease. The underlying cause for anemia probably is multifactorial, including reduced sensitivity to erythropoietin receptors, the presence of a hematopoiesis inhibitor, and/or a defective iron supply for erythropoiesis as possible explanations.

A standard diagnostic workup should be undertaken in anemic patients with HF, with the recognition that no definite etiologic disorder can be identified in many cases. Correctable causes of anemia should be treated in accordance with practice guidelines. The role of blood transfusions in patients with cardiovascular disease is controversial. Although a "transfusion threshold" for maintaining the hematocrit above 30% in patients with cardiovascular disease generally has been accepted, this clinical practice has been based more on expert opinion rather than on direct evidence that documents the efficacy of this form of therapy. In view of the risks and costs of red blood cell transfusion and the evanescent benefits of blood transfusions in patients with a chronic anemia, coupled with the unclear benefit in patients with HF, the routine use of blood transfusion cannot be recommended for treating the anemia that occurs in stable patients with HF. Correction of iron deficiency in patients with NYHA class II or III HF using intravenous iron (ferric carboxymaltose) improved self-reported patient global assessment and NYHA functional class (as well as 6-minute walk distance and health-related quality of life) in the FAIR-HF trial (Ferinject Assessment in Patients with Iron Deficiency and Chronic Heart Failure).¹¹ Treatment of patients with HF who have mild to moderate anemia (hemoglobin levels 9.0 to 12.0 g/dL) with the erythropoietin analog darbepoetin alfa was evaluated in the RED-HF (Reduction of Events with Darbepoetin Alfa in Heart Failure) trial. As shown in Figure 25-4A, there was no significant difference in the primary outcome variable of death from any cause or hospitalization for worsening HF (hazard ratio [HR] in the darbepoetin alfa group, 1.01 [95% confidence interval {CI}, 0.90 to 1.13]; $P = .87$), or in the secondary outcome (Fig. 25-4B) of cardiovascular death or time to first hospitalization for worsening HF (HR in the darbepoetin alfa group, 10.01 [95% CI, 0.89 to 1.14]; $P = .2$). The lack of effect of darbepoetin alfa was consistent across all prespecified subgroups. Of importance, treatment with darbepoetin alfa led to an early (within 1 month) and sustained increase in the hemoglobin level throughout the study. No significant difference in fatal or nonfatal stroke was found between the treatment and the control groups, but a significant increase ($P = .01$) in thromboembolic adverse events was observed in the darbepoetin alfa group (13.5%) compared with the placebo group (10.0%). These results of the RED-HF trial suggest that hemoglobin level, like other HF surrogate endpoints, may be a prognostic marker, with decreased levels correlated with poor prognosis, rather than an HF therapeutic target. Whether intravenous iron will produce symptomatic improvement in iron-deficient patients with HF is the subject of several ongoing clinical trials (ClinicalTrials.gov identifiers: NCT00384657, NCT01394562, NCT01453608).

Renal Insufficiency

Renal insufficiency is associated with poorer outcomes in patients with HF; some uncertainty remains, however, regarding whether renal impairment is a simply a marker for worsening HF or whether renal impairment might be causally linked to worsening HF. Although more common in patients hospitalized for HF, at least some degree of renal impairment is still present in approximately one half of stable outpatients with HF. Patients with renal hypoperfusion or intrinsic renal disease show an impaired response to diuretics and angiotensin-converting enzyme (ACE) inhibitors and are at increased risk for adverse effects during treatment with digitalis. In a recent meta-analysis a majority of patients with HF had some degree of renal impairment. These patients represented a high-risk group with an approximately 50% increased relative mortality risk when compared with patients who had normal renal function.¹² Similar findings were observed in the Acute Decompensated Heart Failure National Registry (ADHERE) (see Chapter 25). In the Second Prospective

FIGURE 25-4 Effect of treatment with darbepoetin alfa on clinical outcomes in patients with HF and mild to moderate anemia. **A**, Kaplan-Meier estimate of the probability of death or HF hospitalization (primary endpoint). **B**, Kaplan-Meier estimate of death from cardiovascular (CV) causes or first hospitalization for HF (secondary endpoint). (Modified from Swedberg K, Young JB, Anand IS, et al: Treatment of anemia with darbepoetin alfa in systolic heart failure. *N Engl J Med* 368:1210, 2013.)

FIGURE 25-5 Effect of renal function on outcomes in patients with HF. Three-dimensional bar graph showing risk of death (vertical axis [y axis]) in relation to decreasing NYHA functional class (x axis) and decreasing quartiles of glomerular filtration rate (GFR) ("axis" back-extending from x axis). (From Hillege HL, Girbes AR, de Kam PJ, et al: Renal function, neurohormonal activation, and survival in patients with chronic heart failure. *Circulation* 102:203, 2000.)

Randomized study of Ibopamine on Mortality and Efficacy, impaired renal function was a stronger predictor of mortality than impaired LV function and NYHA functional class in patients with advanced HF (Fig. 25-5). Thus renal insufficiency is a strong, independent predictor of adverse outcomes in patients with HF.

APPROACH TO THE PATIENT

HF should be viewed as a continuum comprising four interrelated stages, as depicted in Figure 25-6.¹³ Stage A includes patients who are at high risk for developing HF, but without structural heart disease or symptoms of HF (e.g., patients with diabetes or hypertension). Stage B includes patients who have structural heart disease but without symptoms of HF (e.g., patients with a previous MI and asymptomatic LV dysfunction). Stage C includes patients with structural heart disease who have developed symptoms of HF (e.g., patients with a previous MI with shortness of breath and fatigue). Stage D includes patients with treatment-refractory HF requiring special

interventions (e.g., patients with refractory HF who are awaiting cardiac transplantation). A simplified algorithm for the approach to the patient with HF is presented in Figure 25-7. The clinical assessment of patients with HFrEF is discussed in detail in Chapter 23, and the diagnosis and management of patients with HFpEF are discussed in detail in Chapter 27.

Patients at High Risk for Developing Heart Failure

For patients at high risk for development of HF (stage A), every effort should be made to prevent HF, using standard practice guidelines to treat preventable conditions that are known to lead to HF, including hypertension (see Chapter 43), hyperlipidemia (see Chapter 45), and diabetes (see Chapter 61). In this regard, ACE inhibitors are particularly useful in preventing HF in patients who have a history of atherosclerotic vascular disease, diabetes mellitus, or hypertension with associated cardiovascular risk factors.

Population Screening. At present, only limited information is available to support the screening of broad populations to detect undiagnosed HF and/or asymptomatic LV dysfunction. Although initial studies suggested that determination of BNP or NT-proBNP levels (see also Chapter 23) might be useful for screening, the positive predictive value of these tests in a low-prevalence and asymptomatic population for the purpose of detecting cardiac dysfunction varies among studies, and the possibility of false-positive results has significant cost-effectiveness implications.¹⁴

Patients who are at very high risk of a developing cardiomyopathy (e.g., those with a strong family history of cardiomyopathy or those receiving cardiotoxic interventions [see Chapter 69]) are appropriate targets for more aggressive screening such as two-dimensional echocardiography to assess LV function. The routine periodic assessment of LV function in other patients is not currently recommended, however. Several sophisticated clinical scoring systems have been developed to screen for HF in population-based studies, including the Framingham criteria, which screen for HF on the basis of clinical criteria, and the National Health and Nutrition Survey (NHANES) criteria, which use self-reporting of symptoms to identify patients with HF (Table 25-4). As discussed in Chapter 23, however, additional laboratory testing usually is necessary to make a definitive diagnosis of HF when these methodologies are used.

Management of Patients with Symptomatic and Asymptomatic Heart Failure

Transient Left Ventricular Dysfunction

As noted in Chapter 22, the clinical syndrome of HFrEF begins after an initial index event produces a decline in ejection performance of

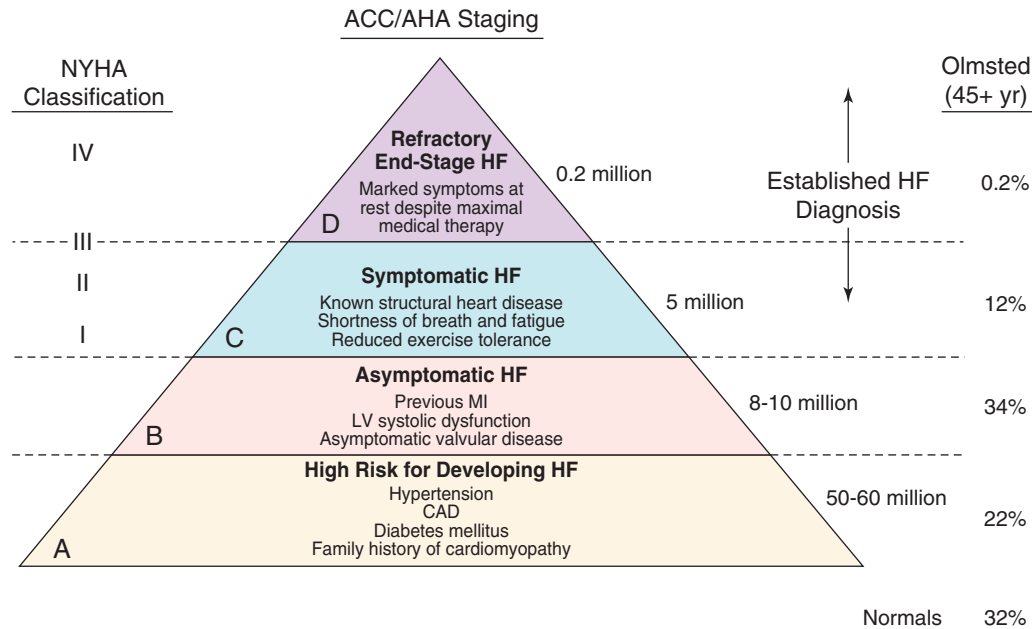

FIGURE 25-6 Stages of HF and their prevalence (data from the Olmstead County Epidemiology Study). Patients in stage A are at high risk for HF but do not have structural heart disease or symptoms of HF. This group includes patients with hypertension, diabetes, CAD, previous exposure to cardiotoxic drugs, or a family history of cardiomyopathy. Patients in stage B have structural heart disease but have no symptoms of HF. This group includes patients with LV hypertrophy, previous MI, LV systolic dysfunction, or valvular heart disease, all of whom would be considered to have NYHA class I symptoms. Patients with stage C HF have known structural heart disease and current or previous symptoms of HF. Their symptoms may be classified as NYHA class I, II, or III. Patients with stage D HF have treatment-refractory symptoms of HF at rest despite maximal medical therapy, are hospitalized, and require specialized interventions or hospice care. All such patients would be considered to have NYHA class IV symptoms. AHA/ACC = American Heart Association/American College of Cardiology. (Modified from Ammar KA, Jacobsen SJ, Mahoney DW, et al: Prevalence and prognostic significance of heart failure stages: application of the American College of Cardiology/American Heart Association heart failure staging criteria in the community. *Circulation* 115:1563, 2007.)

TABLE 25-4 Diagnostic Criteria for Heart Failure in Population-Based Studies

Framingham Criteria		
MAJOR CRITERIA	MINOR CRITERIA	MAJOR OR MINOR CRITERIA
Paroxysmal nocturnal dyspnea or orthopnea	Ankle edema	Weight loss > 4.5 kg in 5 days in response to treatment
Neck-vein distention	Night cough	
Rales	Dyspnea on exertion	
Cardiomegaly	Hepatomegaly	
Acute pulmonary edema	Pleural effusion	
S3 gallop	Vital capacity decreased by one third from maximal capacity	
Increased venous pressure > 16 cm H ₂ O	Tachycardia (rate > 120 beats/min)	
Hepatjugular reflux		

Continued

TABLE 25-4 Diagnostic Criteria for Heart Failure in Population-Based Studies—cont'd

NHANES Criteria		
CATEGORY	CRITERION	SCORE
History	Dyspnea	
	When hurrying on a hill	1
	When walking at an ordinary pace	1
	Do you stop for breath when walking at an ordinary pace?	2
Physical examination	Do you stop for breath when walking after 100 yards on flat ground?	2
	Heart rate	
	91-110 beats/min	1
	>110 beats/min	2
	Jugular venous pressure > 6 cm H ₂ O	
	Alone	1
	PLUS hepatomegaly or edema	2
Rales	Basilar rales	1
	Rales of more extensive distribution (beyond basilar)	2
Chest radiography	Upper zone flow redistribution	1
	Interstitial pulmonary edema	2
	Interstitial edema plus pleural fluid	3
	Alveolar fluid PLUS pleural fluid	3

The diagnosis of HF using the Framingham criteria requires the simultaneous presence of at least 2 major criteria, or 1 major criterion in conjunction with 2 minor criteria. Use of minor criteria is acceptable only if they cannot be attributed to another medical condition (such as pulmonary hypertension, chronic lung disease, cirrhosis, ascites, or the nephrotic syndrome). With the NHANES-1 criteria, diagnosis of HF is made with a score of 3 points or more.
 Modified from Ho KK, Pinsky JL, Kannel WB, et al: The epidemiology of heart failure: The Framingham Study. *J Am Coll Cardiol* 22:6A, 1993; and Schocken DD, Arrieta MI, Leaverton PE, et al: Prevalence and mortality rate of congestive heart failure in the United States. *J Am Coll Cardiol* 20:301, 1992.

FIGURE 25-8 Algorithm for the diagnosis of HF or LV (systolic) dysfunction. (From Swedberg K, Cleland J, Dargie H, et al: Guidelines for the diagnosis and treatment of chronic heart failure: Executive summary (update 2005): the Task Force for the Diagnosis and Treatment of Chronic Heart Failure of the European Society of Cardiology. *Eur Heart J* 26:1115, 2005.)

the heart. Of note, however, LV dysfunction may develop transiently in a variety of different clinical settings that may not invariably lead to the development of the clinical syndrome of HF. **Figure 25-8** illustrates the important relationship between LV dysfunction (transient and sustained) and the clinical syndrome of HF (asymptomatic and symptomatic). LV dysfunction with pulmonary edema may develop acutely in patients with previously normal LV structure and function. This occurs most commonly postoperatively after cardiac surgery or in the setting of severe brain injury, or after a systemic infection. The general pathophysiologic mechanism involved is either some form of “stunning” of functional myocardium (see also **Chapter 49**), or activation of proinflammatory cytokines that are capable of suppressing LV function (see **Chapter 23**). Emotional stress can also precipitate severe, reversible LV dysfunction that is accompanied by chest pain, pulmonary edema, and cardiogenic shock in patients without coronary disease (takotsubo syndrome). In this setting, LV dysfunction is thought to be secondary to the

deleterious effects of catecholamines after heightened sympathetic stimulation.¹⁵ Of note, exercise-induced LV dysfunction, usually caused by myocardial ischemia, also may lead to symptoms by causing a rise in LV filling pressure and a fall in cardiac output in the absence of discernable LV dysfunction at rest. If LV dysfunction persists after the initial cardiac injury, patients may remain asymptomatic for a period of months to years; however, the weight of epidemiologic and clinical evidence suggests that at some point these patients will undergo the transition to overt symptomatic HF.

Defining the Appropriate Strategy

The main goals of treatment for HF are to reduce symptoms, prolong survival, improve the quality of life, and prevent disease progression. As discussed further on, the current pharmacologic, device, and surgical therapeutic armamentarium for the management

of HFrEF permits health care providers to achieve each of these goals in the great majority of patients. As shown in **Table 25-5**, once structural heart disease has developed (stages B to D), the choice of therapy for patients with HFrEF depends on their NYHA functional classification (see **Chapter 23** and **Table 23-1**). Although this classification system is notoriously subjective, with large degree of interobserver variability, it has withstood the test of time and continues to be widely applied to patients with HF. For patients who have developed LV systolic dysfunction but remain asymptomatic (NYHA class I), the goal should be to slow disease progression by blocking neurohormonal systems that lead to cardiac remodeling (see **Chapter 22**). For patients who have developed symptoms (NYHA class II to IV), the primary goal should be to alleviate fluid retention, lessen disability, and reduce the risk of further disease progression and death. As discussed subsequently, these goals generally require a strategy that combines diuretics (to control salt and water retention) with neurohormonal interventions (to minimize cardiac remodeling).

TABLE 25-5 Pharmacologic and Device Therapy in Patients with Chronic Heart Failure

INDICATION	ACE INHIBITOR	ARB	DIURETIC	BETA BLOCKER	ALDOSTERONE ANTAGONIST	CARDIAC GLYCOSIDES	CRT	ICD
Asymptomatic LV dysfunction (NYHA class I)	Indicated	If patient is ACE-intolerant	Not indicated	Post-MI Indicated*	Recent MI	(1) For rate control with atrial fibrillation or (2) when improved from more severe HF and in sinus rhythm	May be considered*	Indicated
Symptomatic HF (NYHA class II)	Indicated	Indicated with or without ACE inhibitor	Indicated if fluid retention present	Indicated	Indicated		Indicated†	
Worsening HF (NYHA class III-IV)	Indicated	Indicated with or without ACE inhibitor	Indicated, combination of diuretics	Indicated (under specialist care)	Indicated	Indicated	Indicated‡	Indicated
End-stage HF (NYHA class IV)	Indicated	Indicated with or without ACE inhibitor	Indicated, combination of diuretics	Indicated (under specialist care)	Indicated	Indicated	Indicated‡	Not indicated§

*May be considered in patients with LVEF 30% or less, of ischemic etiology, in sinus rhythm with a QRS of 150 milliseconds or longer with LBBB morphology.

†Indicated with QRS of 130 milliseconds or longer with LBBB morphology, or QRS of 150 milliseconds or longer with non-LBBB morphology and EF of 30% or less.

‡Indicated with QRS of 120 milliseconds or more with LBBB or QRS of 150 milliseconds or longer with non-LBBB morphology and EF of 35% or less.

§Use of an ICD may be considered in patients with NYHA class IV HF who are undergoing implantation of a CRT device.

CRT = cardiac resynchronization therapy; ICD = implantable cardioverter defibrillator.

Details on recommendations for ICD and CRT implantation are given in the [Chapter 26](#) Guidelines ("Cardiac Resynchronization and Implantable Cardioverter Defibrillators in Heart Failure with a Reduced Ejection Fraction").

Modified from Swedberg K, Cleland J, Dargie H, et al: *Guidelines for the diagnosis and treatment of chronic heart failure: Executive summary (update 2005): the Task Force for the Diagnosis and Treatment of Chronic Heart Failure of the European Society of Cardiology*. *Eur Heart J* 26:1115, 2005.

General Measures

Identification and correction of the condition(s) responsible for the cardiac structural and/or functional abnormalities are critical (see [Table 25-2](#)), insofar as some of conditions that provoke LV structural and functional abnormalities are potentially treatable and/or reversible. Furthermore, clinicians should aim to aggressively screen for and treat comorbid illnesses hypertension and diabetes that are believed to underlie the structural heart disease. In addition to searching for reversible etiologic disorders and comorbid conditions that contribute to the development of HF, it is equally important to identify factors that provoke worsening HF in previously stable patients ([Table 25-6](#)). Among the most common causes of acute decompensation in a previously stable patient are dietary indiscretion and inappropriate reduction of HF therapy, from either self-discontinuation of medication or, alternatively, from physician withdrawal of effective pharmacotherapy (e.g., because of concern over azotemia). Patients with HF should be advised to stop smoking and to limit alcohol consumption to two standard drinks per day in men or one standard drink per day in women. Patients suspected of having an alcohol-induced cardiomyopathy should be advised to abstain from alcohol consumption indefinitely. Excessive temperature extremes and heavy physical exertion should be avoided. Certain drugs that are known to make HF worse also should be avoided. For example, nonsteroidal anti-inflammatory drugs (NSAIDs), including cyclooxygenase-2 (COX-2) inhibitors, are not recommended in patients with chronic HF because the risk of renal failure and fluid retention as side effects is markedly increased in the setting of reduced renal function and/or ACE inhibitor use. Patients should be advised to weigh themselves on a regular basis to monitor for weight gain and to alert a health care provider or adjust their diuretic dose in the case of a sudden unexpected weight gain of more than 3 to 4 pounds over a 3-day period. Although documented evidence of the effects of immunization in patients with HF is lacking, these

TABLE 25-6 Factors That May Precipitate Acute Decompensation in Patients with Chronic Heart Failure

Dietary indiscretion
Inappropriate dose reduction/discontinuation of HF medications
Myocardial ischemia/infarction
Arrhythmias (tachycardia or bradycardia)
Infection
Anemia
Initiation of medications that worsen the symptoms of HF
Calcium antagonists (verapamil, diltiazem)
Beta blockers
NSAIDs
Thiazolidinediones
Antiarrhythmic agents (all class I agents, sotalol [class III])
Anti-TNF antibodies
Alcohol consumption
Pregnancy
Worsening hypertension
Acute valvular insufficiency

patients are at high risk for developing pneumococcal pneumonia and influenza. Accordingly, clinicians should consider recommending influenza and pneumococcal vaccines to their patients with HF, to prevent respiratory infections. It is equally important to educate the patient with HF and family about the importance of proper diet, as well as of compliance with the medical regimen. Supervision of outpatient care by a specially trained nurse or physician assistant and/or specialized HF clinics have been found to be helpful, particularly in patients with advanced disease (see later under Disease Management).

Activity

Although heavy physical labor is not recommended in HF, routine modest exercise has been shown to be beneficial in selected patients with NYHA class I to III HF. The HF-ACTION (A Controlled Trial Investigating Outcomes of Exercise Training) trial was a large multicenter randomized controlled study for which the primary endpoint was a composite of all-cause mortality and all-cause hospitalization. Secondary endpoints included all-cause mortality, all-cause hospitalization and the composite of cardiovascular mortality or cardiovascular hospitalization, and the composite of cardiovascular mortality or HF-related hospitalization. HF-ACTION failed to show a significant improvement in all-cause mortality or all-cause hospitalization (hazard ratio [HR], 0.93 [95% CI, 0.84 to 1.02]; $P = .13$) in patients who received a 12-week (three times a week) exercise training program followed by 25- to 30-minute home-based, self-monitored exercise workouts, 5 days/week, on a treadmill or stationary bicycle (Fig. e25-1A). Moreover, there was no difference in all-cause mortality (HR, 0.96 [95% CI, 0.79 to 1.17]; $P = .70$) (Fig. e25-1B). A trend toward decreased cardiovascular mortality or HF-related hospitalizations (HR, 0.87 [95% CI, 0.74 to 0.99]; $P = .06$) was observed, however, and quality of life was significantly improved in the exercise group.¹⁶ For euvoletic patients, regular isotonic exercise such as walking or riding a stationary-bicycle ergometer may be useful as an adjunctive therapy to improve clinical status after exercise testing has determined the safety of such training (i.e., the patient does not develop significant ischemia or arrhythmias). Exercise training is not recommended, however, in patients with HFrEF who have had a major cardiovascular event or procedure within the past 6 weeks; in patients receiving cardiac devices that limit the ability to achieve target heart rates; or in patients with significant arrhythmia or ischemia during baseline cardiopulmonary exercise testing.

Diet

Dietary restriction of sodium (to 2 to 3 g daily) is recommended in all patients with the clinical syndrome of HF and either preserved or depressed EF. Further restriction (<2 g daily) may be considered in moderate to severe HF. Fluid restriction generally is unnecessary except in the setting of hyponatremia (<130 mEq/liter), which may develop as a consequence of activation of the renin-angiotensin system, excessive secretion of AVP, or loss of salt in excess of water from previous diuretic use. Fluid restriction (<2 liters/day) should be considered in hyponatremic patients (<130 mEq/liter), or for those patients whose fluid retention is difficult to control despite high doses of diuretics and sodium restriction. Caloric supplementation is recommended for patients with advanced HF and unintentional weight loss or muscle wasting (cardiac cachexia); however, anabolic steroids are not recommended for these patients because of the potential problems with volume retention. The measurement of nitrogen balance, caloric intake, and prealbumin may be useful in determining appropriate nutritional supplementation. The use of dietary supplements ("nutriceuticals") should be avoided in the management of symptomatic HF because of the lack of proven benefit and the potential for significant interactions with proven HF therapeutics.

MANAGEMENT OF FLUID RETENTION

Many of the clinical manifestations of the syndrome of HF result from excessive salt and water retention that leads to an inappropriate

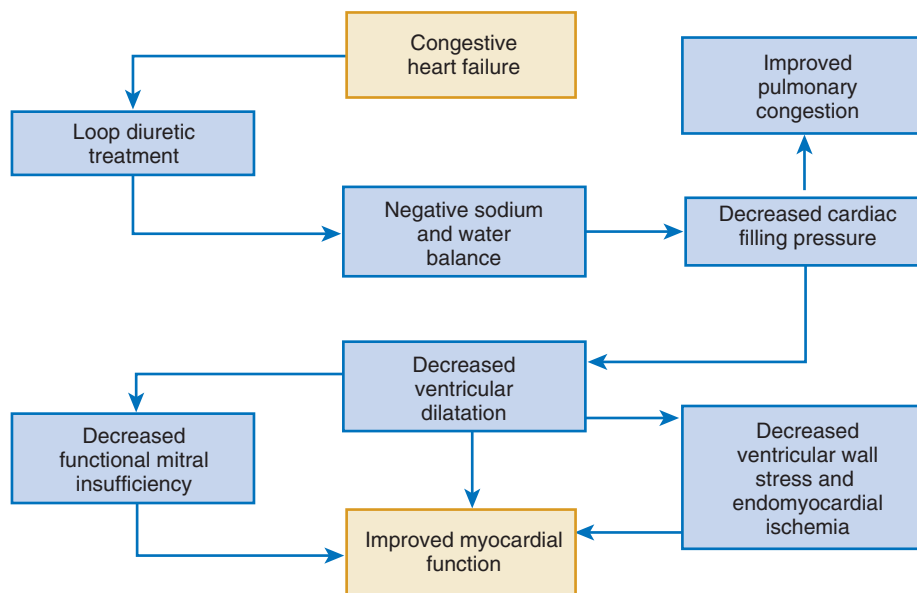

FIGURE 25-9 Potential beneficial effects of diuretics on myocardial function. Diuretic-induced negative sodium and water balance can decrease LV dilation, ameliorate functional mitral insufficiency, and decrease mitral wall stress and subendocardial ischemia. Treatment with diuretics, however, also can lead to deterioration of renal function and worsening neurohormonal activation. (Modified from Schrier RW: Use of diuretics in heart failure and cirrhosis. *Semin Nephrol* 31:503, 2011.)

volume expansion of the vascular and extravascular space. Moreover, diuretic-induced negative sodium and water balance can decrease LV dilation, help correct functional mitral insufficiency, and reduce mitral wall stress and degree of subendocardial ischemia (Fig. 25-9). Although both digitalis and low doses of ACE inhibitors enhance urinary sodium excretion, few volume-overloaded patients with HF can maintain proper sodium balance without the use of diuretic drugs. Indeed, attempts to substitute ACE inhibitors for diuretics have been shown to lead to pulmonary edema and peripheral congestion. In short-term clinical trials, diuretic therapy has led to reductions in jugular venous pressures, pulmonary congestion, peripheral edema, and body weight, all of which were observed within days of initiation of therapy. In intermediate-term studies, diuretics have been shown to improve cardiac function, relieve symptoms, and increase exercise tolerance in patients with HF.¹⁷ To date, no long-term studies of diuretic therapy in HF have been performed, so the effects of these agents on morbidity and mortality are not clearly known. Although retrospective analyses of clinical trials suggest that diuretic use is associated with worse clinical outcomes,¹⁷ a meta-analysis (Cochrane Review) suggested that treatment with diuretic therapy produced a significant reduction in mortality (odds ratio [OR], 0.24 [95% CI, 0.07 to 0.83]; $P = .02$) and worsening HF (OR, 0.07 [95% CI, 0.01 to 0.52]; $P = .01$).¹⁷ In view of its retrospective nature, however, this analysis cannot be used as formal evidence to recommend the use of diuretics to reduce HF-related mortality.

Diuretic Classes

A number of classification schemes have been proposed for diuretics on the basis of their mechanism of action, their anatomic locus of action within the nephron, and the form of diuresis that they elicit ("solute diuresis" versus "water diuresis"). The most common classification for diuretics uses an admixture of chemical designation (e.g., thiazide diuretic), site of action (e.g., loop diuretics), and clinical outcome (e.g., potassium-sparing diuretics). The loop diuretics increase sodium excretion by up to 20% to 25% of the filtered load of sodium, enhance free water clearance, and maintain their efficacy unless renal function is severely impaired. In contrast, the thiazide diuretics increase the fractional excretion of sodium to only 5% to 10% of the filtered load, tend to decrease free water clearance, and lose their effectiveness in patients with impaired renal function

FIGURE e25-1 Kaplan-Meier analysis of the effect of exercise versus usual care on HF-related morbidity and mortality in the HF-ACTION trial. **A**, Time to all-cause mortality or all-cause hospitalization; **B**, time to all-cause mortality. (From O'Connor, CM, Whellan DJ, Lee KL, et al: Efficacy and safety of exercise training in patients with chronic heart failure: HF-ACTION randomized controlled trial. *JAMA* 301:1439, 2009.)

(creatinine clearance less than 40 mL/min). Consequently, the loop diuretics have emerged as the preferred diuretic agents for use in most patients with HF. Diuretics that induce a water diuresis ("aquaretics") include demeclocycline, lithium, and vasopressin V_2 receptor antagonists, each of which inhibits the action of AVP on the collecting duct through different mechanisms, thereby increasing free water clearance. Drugs that cause solute diuresis are subdivided into two types: osmotic diuretics, which are nonresorbable solutes that osmotically retain water and other solutes in the tubular lumen, and drugs that selectively inhibit ion transport pathways across tubular epithelia, which constitute a majority of potent, clinically useful diuretics. The classes of diuretics and individual agents are listed in [Table 25-7](#), and their renal sites of action are depicted in [Figure 25-10](#).

Loop Diuretics

The agents classified as loop diuretics, including furosemide, bumetanide, and torsemide, act by reversibly inhibiting the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter (cotransporter) on the apical membrane of epithelial cells in the thick ascending loop of Henle (site II in [Fig. 25-10](#)). Because furosemide, bumetanide, and torsemide are bound extensively to plasma proteins, delivery of these drugs to the tubule by filtration is limited. However, these drugs are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to their binding sites on the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter

in the luminal membrane of the ascending limb. Thus the efficacy of loop diuretics is dependent on sufficient renal plasma blood flow and proximal tubular secretion to deliver these agents to their site of action. Probenecid shifts the plasma concentration-response curve for furosemide to the right by competitively inhibiting furosemide excretion by the organic acid transport system. The bioavailability of furosemide ranges from 40% to 70% of the oral dose. By contrast, the oral bioavailability of bumetanide and torsemide exceeds 80%. Accordingly, these agents may be more effective in advanced HF or right-sided HF, albeit at considerably greater cost. Agents in a second functional class of loop diuretics typified by ethacrynic acid exhibit a slower onset of action, with delayed and only partial reversibility. Ethacrynic acid may be safely used in sulfa-allergic patients with HF.

Mechanisms of Action of Loop Diuretics. Loop diuretics are believed to relieve symptoms of congestion by several mechanisms. First, loop diuretics reversibly bind to and reversibly inhibit the action of the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter, thereby preventing salt transport in the thick ascending loop of Henle. Inhibition of this symporter also inhibits Ca^{2+} and Mg^{2+} resorption by abolishing the transepithelial potential difference that is the driving force for absorption of these cations. By inhibiting the concentration of solute within the medullary interstitium, these drugs also reduce the driving force for water resorption in the collecting duct, even in the presence of AVP ([see also Chapters 23 and 24](#)). The decreased resorption of water by the

TABLE 25-7 Diuretics for Treating Fluid Retention in Chronic Heart Failure

DRUG	INITIAL DAILY DOSE(S)	MAXIMUM TOTAL DAILY DOSE	DURATION OF ACTION
Loop Diuretics*			
Bumetanide	0.5-1.0 mg once or twice	10 mg	4-6 hours
Furosemide	20-40 mg once or twice	600 mg	6-8 hours
Torsemide	10-20 mg once	200 mg	12-16 hours
Ethacrynic acid	25-50 mg once or twice	200 mg	6 hours
Thiazide Diuretics†			
Chlorthiazide	250-500 mg once or twice	1000 mg	6-12 hours
Chlorthalidone	12.5-25 mg once	100 mg	24-72 hours
Hydrochlorthiazide	25 mg once or twice	200 mg	6-12 hours
Indapamide	2.5 mg once	5 mg	36 hours
Metolazone	2.5-5.0 mg once	20 mg	12-24 hours
Potassium-Sparing Diuretics			
Amiloride	12.5-25 mg once	20 mg	24 hours
Triamterene	50-75 mg twice	200 mg	7-9 hours
AVP Antagonists			
Satavaptan	25 mg once	50 mg	NS
Tolvaptan	15 mg once	60 mg	NS
Lixivaptan	125 mg once	250 mg	NS
Conivaptan (IV)	20 mg IV loading dose, followed by 20 mg/day continuous IV infusion	40 mg IV infusion/day	7-9 hours
Sequential Nephron Blockade			
Metolazone	2.5-10 mg once PLUS loop diuretic		
Hydrochlorothiazide	25-100 mg once or twice PLUS loop diuretic		
Chlorothiazide (IV)	500-1000 mg once PLUS loop diuretic		

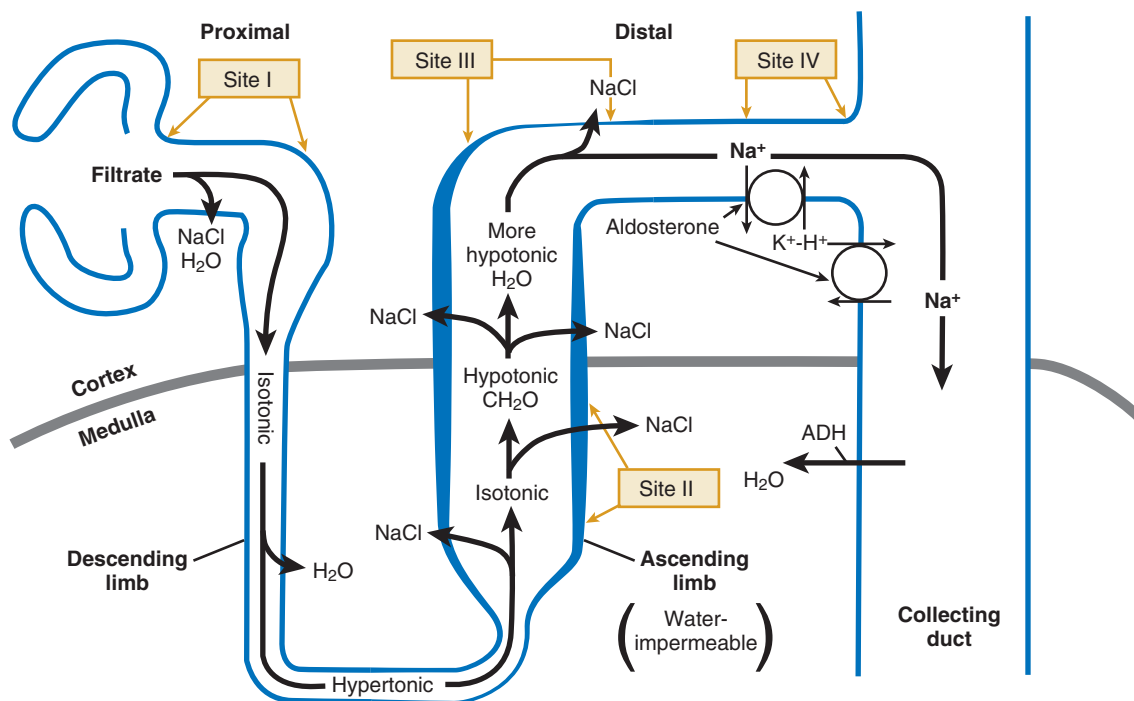

*Equivalent doses: 40 mg furosemide = 1 mg bumetanide = 20 mg torsemide = 50 mg of ethacrynic acid.

†Do not use if estimated glomerular filtration rate is <30 mL/min or with cytochrome 3A4 inhibitors.

Unless indicated, all doses are for oral diuretics.

IV, intravenous; NS = not specified.

collecting duct results in the production of urine that is nearly isotonic with plasma. The increase in delivery of Na^+ and water to the distal nephron segments also markedly enhances K^+ excretion, particularly in the presence of elevated aldosterone levels.

Loop diuretics also exhibit several characteristic effects on intracardiac pressure and systemic hemodynamics. Furosemide acts as a venodilator and reduces right atrial and pulmonary capillary wedge pressure within minutes when given intravenously (0.5 to 1.0 mg/kg). Similar data, although not as extensive, have accumulated for bumetanide and torsemide. This initial improvement in hemodynamics may be secondary to the release of vasodilatory prostaglandins, insofar as studies in animals and humans have demonstrated that the venodilatory actions of furosemide are inhibited by indomethacin. There have also been reports of an acute rise in systemic vascular resistance in response to loop diuretics, which has been attributed to transient activation of the systemic or intravascular renin-angiotensin system. The potentially deleterious rise in LV afterload reinforces the importance of initiating vasodilator therapy with diuretics in patients with acute pulmonary edema and adequate blood pressure (see [Chapter 24](#)).

Thiazide and Thiazide-like Diuretics

The benzothiadiazides, also known as thiazide diuretics, were the initial class of drugs that were synthesized to block the $\text{Na}^+\text{-Cl}^-$ transporter in the cortical portion of the ascending loop of Henle and the distal convoluted tubule (site III; see [Fig. 25-10](#)). Subsequently, drugs that share similar pharmacologic properties became known as thiazide-like diuretics, even though they were technically not benzothiadiazine derivatives. Metolazone, a quinazoline sulfonamide, is a thiazide-like diuretic that is used in combination with furosemide in patients who become resistant to diuretics (see further on). Because thiazide and thiazide-like diuretics prevent maximal dilution of urine, they decrease the kidney's ability to increase free water clearance, potentially contributing to the development of hyponatremia. Thiazides increase Ca^{2+} resorption in the distal nephron (see [Fig. 25-10](#))

by several mechanisms, occasionally resulting in a small increase in serum Ca^{2+} levels. By contrast, Mg^{2+} resorption is diminished, and hypomagnesemia may occur with prolonged use. Increased delivery of NaCl and fluid into the collecting duct directly enhances K^+ and H^+ secretion by this segment of the nephron, which may lead to clinically important hypokalemia.

Mechanisms of Action of Thiazide and Thiazide-like Diuretics. The site of action of these drugs within the distal convoluted tubule has been identified as the local $\text{Na}^+\text{-Cl}^-$ symporter. Although this cotransporter shares approximately 50% amino acid homology with the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter of the ascending limb of the loop of Henle, it is insensitive to the effects of furosemide. This cotransporter (or related isoforms) also is present on cells within the vasculature, and on many cell types within other organs and tissues, and may contribute to some of the other actions of these agents, such as their usefulness as antihypertensive agents. As with the loop diuretics, the efficacy of thiazide diuretics is dependent, at least in part, on proximal tubular secretion to deliver these agents to their site of action. Unlike with the loop diuretics, however, the plasma protein binding varies considerably among the thiazide diuretics; accordingly, this parameter will determine the contribution of glomerular filtration to tubular delivery of a specific diuretic.

Mineralocorticoid Receptor Antagonists

Mineralocorticoids, such as aldosterone, cause retention of salt and water and increase the excretion of K^+ and H^+ by binding to specific mineralocorticoid receptors. Spironolactone and eplerenone are synthetic mineralocorticoid receptors that act on the distal nephron to inhibit $\text{Na}^+\text{-K}^+$ excretion at the site of aldosterone action (see [Fig. 25-10](#)).

Mechanisms of Action of Mineralocorticoid Receptor Antagonists. Spironolactone has antiandrogenic and progesterone-like effects, which may cause gynecomastia or impotence in men, and

menstrual irregularities in women. To overcome these side effects, eplerenone was developed by replacing the 17- α -thioacetyl group of spironolactone with a carbomethoxy group. As a result of this modification, eplerenone has greater selectivity for the mineralocorticoid receptor than for steroid receptors, with fewer sex hormone side effects than for spironolactone. Eplerenone is further distinguished from spironolactone by its shorter half-life and the fact that it does not have any active metabolites. Although spironolactone and eplerenone are weak diuretics, clinical trials have shown that both agents have profound effects on cardiovascular morbidity and mortality (Fig. 25-11) by virtue of their ability to antagonize the deleterious effects of aldosterone in the cardiovascular system (see Chapter 22). Hence these agents are used in HF for their ability to antagonize the renin-angiotensin-aldosterone system (see further on), rather than for their diuretic properties. Spironolactone (see Table 25-7) and its active metabolite, canrenone, competitively inhibit the binding of aldosterone to mineralocorticoid or type I receptors in many tissues, including epithelial cells of the distal convoluted tubule and collecting duct.

A

B

FIGURE 25-11 Kaplan-Meier analysis of the probability of survival among patients in the placebo and treatment groups in the RALES trial (**A**) with spironolactone and in the EMPHASIS trial (**B**) using eplerenone. (Modified from Pitt B, Zannad F, Remme WJ, et al: The effect of spironolactone on morbidity and mortality in patients with severe heart failure. Randomized Aldactone Evaluation Study Investigators. *N Engl J Med* 341:709, 1999; and Zannad F, McMurray JJ, Krum H, et al: Eplerenone in patients with systolic heart failure and mild symptoms. *N Engl J Med* 364:11, 2011.)

These cytosolic receptors are ligand-dependent transcription factors, which upon binding of the ligand (e.g., aldosterone) translocate to the nucleus, where they bind to hormone response elements present in the promoter of some genes, including several involved in vascular and myocardial fibrosis, inflammation, and calcification.

Potassium-Sparing Diuretics

Triamterene and amiloride are referred to as *potassium-sparing diuretics*. These agents share the common property of causing a mild increase in NaCl excretion, as well as having antialkalemic properties. Triamterene is a pyrazinoylguanidine derivative, whereas amiloride is a pteridine. Both drugs are organic bases that are transported into the proximal tubule, where they block Na^+ reabsorption in the late distal tubule and collecting duct (site IV in Fig. 25-10). However, because Na^+ retention occurs in more proximal nephron sites in HF, neither amiloride nor triamterene is effective in achieving a net negative Na^+ balance when given alone in patients with HF. Both amiloride and triamterene appear to share similar mechanisms of action. Considerable evidence suggests that amiloride blocks Na^+ channels in the luminal membrane of the principal cells in the late distal tubule and collecting duct, perhaps by competing with Na^+ for negatively charged areas within the pore of the Na^+ channel. Blockade of Na^+ channels leads to hyperpolarization of the luminal membrane of the tubule, which reduces the electrochemical gradient that provides the driving force for K^+ secretion into the lumen. Amiloride and its congeners also inhibit Na^+/H^+ antiporters in renal epithelial cells and in many other cell types, but only at concentrations that are higher than those used clinically.

Carbonic Anhydrase Inhibitors

The zinc metalloenzyme carbonic anhydrase plays an essential role in NaHCO_3^- resorption and acid secretion in the proximal tubule (site I in Fig. 25-10). Although weak diuretics, carbonic anhydrase inhibitors (see Table 25-7) such as acetazolamide potentially inhibit carbonic anhydrase, resulting in near complete loss of NaHCO_3^- resorption in the proximal tubule. The use of these agents in patients with HF is confined to temporary administration to correct the metabolic alkalosis that occurs as a “contraction” phenomenon in response to the administration of other diuretics. When used repeatedly, these agents can lead to metabolic acidosis as well as severe hypokalemia.

Vasopressin Antagonists

As discussed in Chapter 22, increased circulating levels of the pituitary hormone AVP contribute to the increased systemic vascular resistance and positive water balance seen in patients with HF. The cellular effects of AVP are mediated by interactions with three types of receptors: V_{1a} , V_{1b} , and V_2 (see Chapter 22). V_{1a} -selective receptor-antagonists block the vasoconstricting effects of AVP in peripheral vascular smooth muscle cells, whereas V_2 -selective receptor antagonists inhibit recruitment of aquaporin water channels into the apical membranes of collecting duct epithelial cells, thereby reducing the ability of the collecting duct to resorb water (Fig. 25-12). Combined V_{1a} - V_2 antagonists lead to a decrease in systemic vascular resistance and prevent the dilutional hyponatremia that occurs in patients with HF.¹⁸

The AVP antagonists, or “vaptans” (see Table 25-7), were developed to block selectively the V_2 receptor (e.g., tolvaptan, lixivaptan, satavaptan) or nonselectively block both the V_{1a} and V_2 receptors (e.g., conivaptan). All four AVP antagonists increase urine volume, decrease urine osmolality, and have no effect on 24-hour sodium excretion (see also Chapter 24).¹⁸ Long-term therapy with the V_2 -selective vasopressin antagonist tolvaptan did not reduce mortality but appears to be safe in patients with advanced HF (see Chapter 24).¹⁹ Currently, two vasopressin antagonists—conivaptan and tolvaptan—are FDA (U.S. Food and Drug Administration)-approved for the treatment of clinically significant hypervolemic and euvoletic hyponatremia (serum $\text{Na}^+ \leq 125$) that is symptomatic and resisted correction with fluid restriction in patients with HF; however, neither drug is currently specifically approved for the treatment of HF. Use of these agents is appropriate after traditional measures to treat hyponatremia have

FIGURE 25-12 Mechanism of action of vasopressin antagonists. The binding of AVP to V_2 receptors stimulates the synthesis of aquaporin-2 water channel proteins (AQP) and promotes their transport to the apical surface. At the cell membrane, aquaporin-2 permits selective free water reabsorption down the medullary osmotic gradient, ultimately decreasing serum osmolarity and increasing fluid balance. V_2 antagonists work by preventing AVP from binding to its cognate receptor. cAMP = cyclic adenosine monophosphate; Gs = stimulatory G protein of adenyl cyclase; PKA = protein kinase A. (Modified from deGoma EM, Vagelos RH, et al: *Emerging therapies for the management of decompensated heart failure: from bench to bedside*. *J Am Coll Cardiol* 48:2397, 2006.)

been tried, including water restriction and maximization of medical therapies such as administration of ACE inhibitors or ARBs, which block or decrease angiotensin II. The use of vaptans in patients hospitalized with HF is discussed in [Chapter 24](#).

Diuretic Treatment of Heart Failure

Patients with evidence of volume overload or a history of fluid retention should be treated with a diuretic to relieve their symptoms. In symptomatic patients, diuretics should be always used in combination with neurohormonal antagonists that are known to prevent disease progression. When patients have moderate to severe symptoms or renal insufficiency, a loop diuretic is generally required. Diuretics should be initiated in low doses (see [Table 25-7](#)) and then titrated upward to relieve signs and symptoms of fluid overload. A typical starting dose of furosemide for patients with systolic HF and normal renal function is 40 mg, although doses of 80 to 160 mg often are necessary to achieve adequate diuresis. Because of the steep dose-response curve and effective threshold for loop diuretics ([Fig. 25-13](#)), it is critical to find an adequate dose of loop diuretic that leads to a clear-cut diuretic response. One commonly used method for finding the appropriate dose is to double the dose until the desired effect is achieved, or the maximal dose of diuretic is reached. Once patients have achieved an adequate diuresis, it is important to document their “dry weight”; thereafter, patients should weigh themselves daily in order to maintain this ideal weight.

Although furosemide is the most commonly used loop diuretic, the oral bioavailability of furosemide is approximately 40% to 79%. Therefore bumetanide or torsemide may be preferable because of a relatively greater bioavailability. With the exception of torsemide, the commonly used loop diuretics are short-acting (<3 hours). For this reason, loop diuretics usually need to be given at least twice daily. In some patients, hypotension or azotemia may develop during diuretic therapy. The rapidity of diuresis should then be slowed, but diuretic therapy should be maintained at a lower level until the patient becomes euvolemic, because persistent volume overload may compromise the effectiveness of some neurohormonal antagonists.

FIGURE 25-13 Dose-response curves for loop diuretics. **A**, Fractional sodium excretion (FE_{Na}) as a function of loop diuretic concentration. Compared with normal patients, patients with chronic renal failure (CRF) show a rightward shift in the curve, owing to impaired diuretic secretion. The maximal response is preserved when expressed as FE_{Na} , but not when expressed as absolute sodium excretion. Patients with HF demonstrate a rightward and downward shift, even when the response is expressed as FE_{Na} , and thus are relatively diuretic-resistant. **B**, Comparison of the response to intravenous and oral doses of loop diuretics in normal subjects and in patients with HF. Diuretic bioavailability is shown for both groups. The natriuretic threshold necessary to produce a diuresis is shown for normal subjects (dotted line) and for patients with HF (solid line). In a normal subject, an oral dose may be as effective as an intravenous dose because the diuretic bioavailability (area under the curve) that is above the natriuretic threshold is approximately the same for intravenous and oral diuretics. However, if the natriuretic threshold increases in a patient with HF, then the oral dose may not provide a high-enough serum level to elicit a significant natriuresis. CHF = congestive heart failure. (Modified from Ellison DH: *Diuretic therapy and resistance in congestive heart failure*. *Cardiology* 96:132, 2001.)

Intravenous administration of diuretics may be necessary to relieve congestion acutely ([Fig. 25-13B](#)) (see [Chapter 24](#)) and can be done safely in the outpatient setting. After a diuretic effect is achieved with short-acting loop diuretics, increasing administration frequency to twice or even three times per day will provide more diuresis with less physiologic perturbation than with larger single doses. Once the congestion has been relieved, treatment with diuretics is continued to prevent the recurrence of salt and water retention, in order to maintain the patient's ideal dry weight.

Complications of Diuretic Use

Patients with HF who are receiving diuretics should be monitored for complications of diuretics on a regular basis. The major complications of diuretic use include electrolyte and metabolic disturbances and volume depletion, as well as worsening azotemia. The interval

for reassessment should be individualized according to severity of illness and underlying renal function; the use of concomitant medications such as ACE inhibitors, ARBs, and aldosterone antagonists; the past history of electrolyte disturbances; and/or the need for more aggressive diuresis.

Electrolyte and Metabolic Disturbances

Diuretic use can lead to potassium depletion, which can predispose the patient to significant cardiac arrhythmias. Renal potassium losses from diuretic use also can be exacerbated by the increase in circulating levels of aldosterone observed in patients with advanced HF, as well by the marked increases in distal nephron Na^+ delivery that accompany use of either loop or distal nephron diuretics. The level of dietary salt intake also may contribute to the extent of renal K^+ wasting with diuretics.

In the absence of formal guidelines with respect to the level of maintenance of serum K^+ levels in patients with HF, many experienced clinicians have advocated that the serum K^+ should be maintained between 4.0 and 5.0 mEq/liter, because these patients often are treated with pharmacologic agents that are likely to provoke proarrhythmic effects in the presence of hypokalemia (e.g., digoxin, type III antiarrhythmics, beta-agonists, or phosphodiesterase inhibitors). Hypokalemia can be prevented by increasing K^+ intake with oral potassium chloride (KCl) supplementation. The normal daily dietary K^+ intake is approximately 40 to 80 mEq. To increase this by 50%, therefore, requires an additional 20 to 40 mEq of K^+ supplementation daily. However, in the presence of alkalosis, hyperaldosteronism, or Mg^{2+} depletion, hypokalemia is quite unresponsive to increased dietary intake of K^+ as KCl, and more aggressive replacement is necessary. If supplementation is necessary, oral potassium supplements in the form of KCl extended-release tablets or liquid concentrate should be used whenever possible. Intravenous potassium is potentially hazardous and should be avoided except in emergencies. When appropriate, the use of an aldosterone receptor antagonist also may help prevent the development of hypokalemia.

The use of aldosterone receptor antagonists is often associated with the development of life threatening hyperkalemia, particularly when they are combined with ACE inhibitors and/or ARBs.²⁰ Potassium supplementation generally is stopped after the initiation of aldosterone antagonists, and patients should be counseled to avoid high-potassium-containing foods. However, patients who have required large amounts of potassium supplementation may need to continue receiving supplementation, albeit at a lower dose, particularly when previous episodes of hypokalemia have been associated with ventricular arrhythmias. Diuretics may be associated with multiple other metabolic and electrolyte disturbances, including hyponatremia, hypomagnesemia, metabolic alkalosis, hyperglycemia, hyperlipidemia, and hyperuricemia. Hyponatremia usually is observed in patients with HF associated with a very high degree of renin-angiotensin system activation and/or high AVP levels. Aggressive diuretic use also can lead to hyponatremia. Hyponatremia typically can be treated by more stringent water restriction. Both loop and thiazide diuretics can cause hypomagnesemia, which can aggravate muscle weakness and cardiac arrhythmias. Magnesium replacement should be administered for signs or symptoms hypomagnesemia (arrhythmias, muscle cramps), and can be routinely given (with uncertain benefit) to all subjects receiving large doses of diuretics or requiring large amounts of K^+ replacement. The modest hyperglycemia and/or hyperlipidemia produced by thiazide diuretics is not usually clinically important, and blood glucose and lipids are usually easily controlled using standard practice guidelines. Metabolic alkalosis generally can be treated by increasing KCl supplementation, lowering diuretic doses, or transient use of acetazolamide.

Hypotension and Azotemia

The excessive use of diuretics can lead to a decreased blood pressure, decreased exercise tolerance, and increased fatigue, as well as impaired renal function. Hypotensive symptoms usually resolve after a decrease in the dose or frequency of diuretics in patients who are volume-depleted. In most instances, however, the use of diuretics is

associated with a decrease in blood pressure and/or mild azotemia that do not lead to patient symptoms. In such instances, reductions in the diuretic dose are not necessary, particularly if the patient remains edematous. In some patients with advanced, chronic HF, acceptance of elevated blood urea nitrogen (BUN) and serum creatinine concentrations may be necessary to maintain control of congestive symptoms.

Neurohormonal Activation

Diuretics may increase the activation of endogenous neurohormonal systems in patients with HF, which can lead to disease progression unless patients are receiving treatment with a concomitant neurohormonal antagonist (e.g., ACE inhibitor or beta blocker).

Ototoxicity

Ototoxicity, which is more frequent with ethacrynic acid than with the other loop diuretics, can manifest as tinnitus, hearing impairment, and deafness. Hearing impairment and deafness are usually, but not invariably, reversible. Ototoxicity occurs most frequently with rapid intravenous injections, and least frequently with oral administration.

Diuretic Resistance and Its Management

One of the inherent limitations of diuretics is that they achieve water loss via excretion of solute at the expense of glomerular filtration, which in turn activates a set of homeostatic mechanisms that ultimately limit their effectiveness. In normal subjects, the magnitude of natriuresis after a given dose of diuretic declines over time as a result of the so-called braking phenomenon (Fig. 25-14). Studies have shown that the time-dependent decline in natriuresis for a given diuretic dose is critically dependent on reduction of the extracellular fluid volume, which leads to an increase in solute and fluid reabsorption in the proximal tubule. In addition, contraction of the extracellular volume can lead to stimulation of efferent sympathetic nerves, which reduces urinary Na^+ excretion by reducing renal blood flow, thereby stimulating renin (and ultimately aldosterone) release, which in turn stimulates Na^+ reabsorption along the nephron (see also Chapter 22). The magnitude of the natriuretic effect of potent loop diuretics also may decline in patients with HF, particularly as the disorder progresses. Although the bioavailability of these diuretics generally is not decreased in HF, the potential delay in their rate of absorption may result in peak drug levels within the tubular lumen in the ascending loop of Henle that are insufficient to induce maximal natriuresis (see Fig. 25-13). The use of intravenous formulations may obviate this problem (see Chapter 24). Even with intravenous dosing, however, a rightward shift of the dose-response curve is observed between the diuretic concentration in the tubular lumen and its natriuretic effect in HF (see Fig. 25-13A). Moreover, the maximal effect (ceiling) is lower in HF. This rightward shift has been referred to as “diuretic resistance” and probably is the result of several factors in addition to the braking phenomenon described previously. First, most loop diuretics with the exception of torsemide, are short-acting drugs. Accordingly, after a period of natriuresis, the diuretic concentration in plasma and tubular fluid declines below the diuretic threshold. In this situation, renal Na^+ reabsorption is no longer inhibited and a period of antinatriuresis or postdiuretic NaCl retention ensues. If dietary NaCl intake is moderate to excessive, postdiuretic NaCl retention may overcome the initial natriuresis in patients with excessive activation of the adrenergic nervous system and the renin-angiotensin system. This observation forms the rationale for administering short-acting diuretics several times per day to obtain consistent daily salt and water loss. Second, a loss of renal responsiveness to endogenous natriuretic peptides is seen as HF advances (see Chapter 22). Third, diuretics increase solute delivery to distal segments of the nephron, causing epithelial cells to undergo both hypertrophy and hyperplasia. Although the diuretic-induced signals that initiate changes in distal nephron structure and function are not well understood, chronic loop diuretic administration increases the Na^+ , K^+ -ATPase activity in the distal collecting duct and

FIGURE 25-14 Effects of diuretics on urinary sodium excretion and extracellular fluid volume. **Main graph.** Effects of a loop diuretic on urinary sodium excretion ($U_{Na}V$). Bars represent 6-hour periods before (in Na^+ balance) and after doses of loop diuretic (D). The dotted line indicates dietary sodium intake. The solid black portion of the open bars indicates the amount by which sodium excretion exceeds intake during natriuresis. The hatched areas indicate the amount of positive Na^+ balance after the diuretic effect has worn off. Net Na^+ balance during 24 hours is the difference between the hatched area (postdiuretic NaCl retention) and the solid area (diuretic-induced natriuresis). Chronic adaptation is indicated by progressively smaller peak natriuretic effects (the braking phenomenon) and is mirrored by a return to neutral balance. **Inset.** Effect of a diuretic on body weight, taken as an index of extracellular fluid volume. Note that steady state is reached within 6 to 8 days despite continued diuretic administration. (Modified from Ellison DH: Diuretic therapy and resistance in congestive heart failure. *Cardiology* 96:132, 2001.)

cortical collecting tubule, as well as increases the number of thiazide-sensitive Na^+-Cl^- cotransporters in the distal nephron, which increases the solute resorptive capacity of the kidney as much as threefold.

In patients with HF, an abrupt decline in cardiac and/or renal function or noncompliance with the diuretic regimen or diet may lead to diuretic resistance. Apart from these more obvious causes, it is important to query the patient with regard to concurrent use of drugs that adversely affect renal function, such as NSAIDs and COX-2 inhibitors (see Table 25-6) and certain antibiotics (trimethoprim and gentamicin). The insulin-sensitizing thiazolidinediones (TZDs) also have been linked to increased fluid retention in patients with HF, although the clinical significance of this finding is not known. It has been suggested that TZDs activate proliferator-activated receptor- γ expression in the renal collecting duct, which enhances expression of cell surface epithelial Na^+ channels. Moreover, studies in healthy men have shown that pioglitazone stimulates plasma renin activity that may contribute to increased Na^+ retention. Rarely, drugs such as probenecid, or high plasma concentrations of some antibiotics may compete with the organic ion transporters in the proximal tubule responsible for the transfer of most diuretics from the recirculation into the tubular lumen. The use of increasing doses of vasodilators, with or without a marked decline in intravascular volume as a result of concomitant diuretic therapy, may lower renal perfusion pressure below that necessary to maintain normal autoregulation and glomerular filtration in patients with renal artery stenosis from atherosclerotic disease. Accordingly, a reduction in renal blood flow may occur despite an increase in cardiac output, thereby leading to a decrease in diuretic effectiveness.

A patient with HF may be considered to be resistant to diuretic drugs when moderate doses of a loop diuretic do not achieve the desired reduction in extracellular fluid volume. In outpatients, a common and useful method for treating the diuretic-resistant patient is to administer two classes of diuretic concurrently. Adding a proximal tubule diuretic or a distal collecting tubule diuretic to a regimen of loop diuretics often is dramatically effective. As a general rule, in adding a second class of diuretic, the dose of loop diuretic should not be altered, because the shape of the dose-response curve for loop diuretics is not affected by the addition of other diuretics, and the loop diuretic must be given at an effective dose for it to be effective.

The combination of loop and distal collecting tubule diuretics has been shown to be effective through several mechanisms.²¹ One is that distal collecting tubule diuretics have longer half-lives than loop diuretics and may thus prevent or attenuate postdiuretic $NaCl$ retention. A second mechanism by which distal collecting tubule diuretics potentiate the effects of loop diuretics is by inhibiting Na^+ transport along the proximal tubule, insofar as most thiazide diuretics also inhibit carbonic anhydrase, as well as by inhibiting $NaCl$ transport along the distal renal tubule, which may counteract the increased solute-resorptive effects of the hypertrophied and hyperplastic distal epithelial cells.

The selection of a distal collecting tubule diuretic to use as a second diuretic is a matter of choice. Many clinicians choose metolazone because its half-life is longer than that of some other distal collecting tubule diuretics, and because it has been reported to remain effective even when the glomerular filtration rate is low. However, direct comparisons between metolazone and several traditional thiazides have shown little difference in natriuretic potency when they are included in a regimen with loop diuretics for patients with HF.²² Distal collecting tubule diuretics may be added in full doses (50 to 100 mg/day of hydrochlorothiazide or 2.5 to 10 mg/day of metolazone) (see Table 25-7) when a rapid and robust response is needed. Such an approach, however, is likely to lead to excessive fluid and electrolyte depletion if patients are not followed up extremely closely. One reasonable approach to combination therapy is to achieve control of fluid overload by initially adding full doses of distal collecting tubule diuretic on a daily basis and then decreasing the dose of the distal collecting tubule diuretic to three times weekly, to avoid excessive diuresis.

An alternative strategy in hospitalized patients is to administer the same daily parenteral dose of a loop diuretic by continuous intravenous infusion, which leads to sustained natriuresis secondary to persistently high drug levels within the tubular lumen (see also Chapter 24) and avoids postdiuretic ("rebound") resorption of Na^+ (see Fig. 25-14B). This approach requires the use of a constant-infusion pump but permits more precise control of the natriuretic effect achieved over time, particularly in carefully monitored patients. It also diminishes the potential for a too-rapid decline in intravascular volume and hypotension as well as the risk of ototoxicity in patients given large-bolus intravenous doses of a loop diuretic. A typical continuous furosemide regimen is initiated with a 20- to 40-mg intravenous loading

dose as a bolus injection, followed by a continuous infusion of 5 to 10 mg/hr for a patient who had been receiving 200 mg/day of oral furosemide in divided doses. The DOSE (Diuretic Optimal Strategy Evaluation in Acute Heart Failure) study showed no significant difference in symptoms or renal function when patients with acute decompensated HF were treated with an intravenous bolus of furosemide compared with an intravenous infusion of furosemide (see Chapter 24), suggesting that whichever approach is most likely to reliably produce the desired diuresis should be used.²³

Another common reason for diuretic resistance in advanced HF is the development of the *cardiorenal syndrome* (see also Chapters 24 and 88), which is recognized clinically as worsening renal function that limits diuresis in patients with obvious clinical volume overload.²⁴ In advanced HF, the cardiorenal syndrome frequently is present in patients who have repeated HF hospitalizations, and in whom adequate diuresis is difficult to obtain because of worsening indices of renal function. This impairment in renal function often is dismissed as “pre-renal”; however, when measured carefully, neither cardiac output nor renal perfusion pressure has been shown to be reduced in diuretic-treated patients who develop the cardiorenal syndrome. Of importance, worsening indices of renal function contribute to longer hospital stays and predict higher rates of early rehospitalization and death²⁴ (see Fig. 25-5). The etiologic mechanisms for and treatment of the cardiorenal syndrome remain poorly understood.

Device-Based Therapies for Management of Fluid Status

The use of mechanical methods of fluid removal, such as extracorporeal ultrafiltration, may be needed to achieve adequate control of fluid retention, particularly in patients who become resistant and/or refractory to diuretic therapy (see also Chapter 24). Extracorporeal ultrafiltration removes salt and water isotonicity by driving the patient's blood through a highly permeable filter in an extracorporeal circuit fashioned in arteriovenous or venovenous mode. Alternative extracorporeal methods include continuous hemofiltration, continuous hemodialysis, and continuous hemodiafiltration.²⁵ With slow continuous ultrafiltration, the patient's intravascular fluid volume remains stable as fluid shifts from the extravascular space into the intravascular space, with the result that there is no deleterious activation of neurohormonal systems. Ultrafiltration has been shown to reduce right atrial and pulmonary artery wedge pressures and increase cardiac output, diuresis, and natriuresis without changes in heart rate, systolic blood pressure, renal function, electrolytes, or intravascular volume.²⁶

The Relief for Acutely Fluid-Overloaded Patients With Decompensated Congestive Heart Failure (RAPID-CHF) trial, which was the first randomized controlled trial of ultrafiltration for acute decompensated HF, enrolled 40 patients, who were randomly assigned to receive either usual care (diuretic) or a single 8-hour ultrafiltration procedure (using a proprietary device) in addition to usual care. The primary endpoint was weight loss 24 hours after enrollment. Fluid removal after 24 hours was approximately twice that for the ultrafiltration group.²⁷ The Ultrafiltration versus IV Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) evaluated the long-term safety and efficacy of ultrafiltration therapy (using a proprietary device) compared with intravenous diuretics in a multicenter trial involving 200 patients, who were assessed at entry and at intervals out to 90 days. The primary endpoint of the trial was total weight loss during the first 48 hours of random assignment and the change in dyspnea score during the first 48 hours of randomization. Although the two treatments were similar in their ability to relieve dyspnea, ultrafiltration was associated with significantly greater fluid loss over 48 hours and a lower rate of rehospitalization during the next 90 days.²⁷ The use of ultrafiltration in high-risk patients who are developing the cardiorenal syndrome was explored in CARRESS (Cardiorenal Rescue Study in Acute Decompensated HF) trial, which showed that ultrafiltration resulted in similar weight loss but resulted in an increase in creatinine levels, compared to standard care, and was associated

with more serious adverse events and intravenous catheter-related complications (see Chapter 24).²⁸

Given the cost, need for venous access, and the nursing support necessary to implement ultrafiltration, the role for this intervention will require additional studies to determine its role in the management of volume overload in patients with HF. In addition to extracorporeal methods for relieving volume overload, peritoneal dialysis can be used as a viable alternative therapy for the short-term management of refractory congestive symptoms for patients in whom vascular access cannot be obtained, or for whom appropriate extracorporeal therapies are not available.

PREVENTION OF DISEASE PROGRESSION

Drugs that interfere with the excessive activation of the renin-angiotensin-aldosterone system and the adrenergic nervous system can relieve the symptoms of HF associated with a depressed EF by stabilizing and/or reversing cardiac remodeling (see Chapter 22). In this regard, ACE inhibitors/ARBs and beta blockers have emerged as cornerstones of modern HF therapy for patients with a depressed EF, to prevent disease progression (Table 25-8).

Angiotensin-Converting Enzyme Inhibitors

The evidence is overwhelming for use of ACE inhibitors in symptomatic and asymptomatic patients with a reduced EF (<40%). ACE inhibitors interfere with the renin-angiotensin system by inhibiting the enzyme that is responsible for the conversion of angiotensin I to angiotensin II (see Chapter 22). However, because ACE inhibitors also inhibit kininase II, they may induce the upregulation of bradykinin, which may further enhance the effects of effects of angiotensin suppression. ACE inhibitors stabilize LV remodeling, relieve patient symptoms, prevent hospitalization, and prolong life. Because fluid retention can attenuate the effects of ACE inhibitors, it is preferable to optimize the dose of diuretic first, before institution of the ACE inhibitor regimen. It may be necessary, however, to reduce the dose of diuretic during the initiation of an ACE inhibitor, to prevent symptomatic hypotension. ACE inhibitors should be initiated in low doses, followed by increments in dosing if lower doses have been well tolerated. Titration generally is achieved by doubling doses every 3 to 5 days. The dose of ACE inhibitor should be increased until the doses used are similar to those that have been shown to be effective in clinical trials (see Table 25-8). Higher doses are more effective than lower doses in preventing hospitalization. For stable patients, it is acceptable to add therapy with beta-adrenergic blocking agents before full target doses of either ACE inhibitor are reached. Blood pressure (including postural changes), renal function, and potassium should be evaluated within 1 to 2 weeks after initiation of ACE inhibitors, especially in patients with preexisting azotemia, hypotension, hyponatremia, diabetes mellitus, or in those taking potassium supplements. Abrupt withdrawal of treatment with an ACE inhibitor may lead to clinical deterioration and should therefore be avoided in the absence of life-threatening complications (e.g., angioedema, hyperkalemia).

The effectiveness of ACE inhibitors has been consistently demonstrated in clinical trials in patients with asymptomatic and symptomatic LV dysfunction^{2,14} (Fig. 25-15). These trials recruited a broad variety of subjects, including women and elderly persons, as well as patients with a wide range of causes and severity of LV dysfunction. The consistency of data from the Studies on Left Ventricular Dysfunction (SOLVD) prevention study, Survival and Ventricular Enlargement (SAVE), and Trandolapril Cardiac Evaluation (TRACE) has shown that asymptomatic patients with LV dysfunction are less likely to develop symptomatic HF and to require hospitalizations for HF (Table 25-9) when treated with an ACE inhibitor. ACE inhibitors also have consistently shown benefit for patients with symptomatic LV dysfunction. As shown in Table 25-9, all placebo-controlled chronic HF trials have demonstrated a reduction in mortality. Furthermore, the absolute

TABLE 25-8 Drugs for the Prevention and Treatment for Chronic Heart Failure

AGENT	INITIATING DAILY DOSE	MAXIMAL DAILY DOSE
Angiotensin-Converting Enzyme Inhibitors		
Captopril	6.25 mg 3x	50 mg 3x
Enalapril	2.5 mg twice	10 mg twice
Lisinopril	2.5-5.0 mg once	20 mg once

*Dosing should be based on ideal body weight, age, and renal function.

†Trough level should be 0.5-1 ng/mL, although absolute levels have not been established.

‡Approved in the European Union for the treatment of HF but is not FDA-approved.

Modified from Mann DL: *Heart failure and cor pulmonale*. In Kasper DL, Braunwald E., Fauci AS, et al (eds): *Harrison's Principles of Internal Medicine*. 17th ed. New York, McGraw-Hill, 2007, p 1449.

benefit is greatest in patients with the most severe HF. Indeed, among patients with NYHA class IV HF, the Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS I) had a much larger effect size than the SOLVD treatment trial, which in turn had a larger effect size than the SOLVD prevention trial. Although only three placebo-controlled mortality trials have been conducted in patients with chronic HF, the aggregate data suggest that ACE inhibitors reduce mortality in direct relation to the degree of severity of chronic HF. The Vasodilator in Heart Failure II (V-HeFT-II) trial provided evidence that ACE inhibitors improve the natural history of HF through mechanisms other than vasodilation, inasmuch as subjects treated with enalapril had significantly lower mortality than subjects treated with the vasodilatory combination of hydralazine plus isosorbide dinitrate (which does not directly inhibit neurohormonal systems). Although enalapril is the only ACE inhibitor that has been used in placebo-controlled mortality trials in chronic HF, as shown in Table 25-9, multiple ACE inhibitors have proved to be more or less equally effective when

FIGURE 25-15 Meta-analysis of data on use of ACE inhibitors in patients with HFrEF. **A**, Kaplan-Meier curves for mortality for patients with HFrEF treated with an ACE inhibitor (ACEI) after acute MI (three trials). **B**, Kaplan-Meier curves for mortality for patients with HFrEF treated with an ACE inhibitor in five clinical trials, including postinfarction trials. The benefits of ACE inhibitors were observed early and persisted over the long term. (Modified from Flather MD, Yusuf S, Køber L, et al: *Long-term ACE-inhibitor therapy in patients with heart failure or left-ventricular dysfunction: A systematic overview of data from individual patients. ACE-Inhibitor Myocardial Infarction Collaborative Group. Lancet 355:1575, 2000.*)

administered in oral form within the first week of the ischemic event in MI trials. ACE inhibitors markedly enhance survival in patients with signs or symptoms of HF after MI. In addition to these effects on mortality, ACE inhibitors improve the functional status of patients with HF. By contrast, ACE inhibitors produce only small benefits in exercise capacity. Taken together, these observations support the conclusion that the effects of ACE inhibitors on the natural history of chronic HF, incidence of post-MI LV dysfunction, or the chances of developing HF in high-risk patients represent “class effects” of these agents. Nonetheless, it is worthy of emphasis that patients with a low blood pressure (less than 90 mm Hg systolic) or impaired renal function (serum creatinine greater than 2.5 mg/mL) were not recruited and/or represent a small proportion of patients who participated in these trials. Thus the effectiveness of these agents in this latter patient populations is less well established.

Complications of Angiotensin-Converting Enzyme Inhibitor Use

A majority of the adverse effects of ACE inhibitors are related to suppression of the renin-angiotensin system. The decreases in blood pressure and mild azotemia often seen during the initiation of therapy

are, in general, well tolerated and do not necessitate a decrease in the dose of the ACE inhibitor. If hypotension is accompanied by dizziness, however, or if the renal dysfunction becomes severe, it may be necessary to decrease the dose of the diuretic in the absence of significant fluid retention or, alternatively, to decrease the dose of the ACE inhibitor in the setting of significant fluid retention. Potassium retention also may become problematic if the patient is receiving potassium supplements or a potassium-sparing diuretic. Potassium retention that is not responsive to these measures may require a

reduction in the dose of ACE inhibitor. The side effects of ACE inhibitors that are related to kinin potentiation include a nonproductive cough (in 10% to 15% of patients) and angioedema (in 1% of patients). In patients who cannot tolerate ACE inhibitors because of cough or angioedema, ARBs constitute the next recommended line of therapy. Patients intolerant to ACE inhibitors because of hyperkalemia or renal insufficiency are likely to experience the same side effects with ARBs. The combination of hydralazine and an oral nitrate should be considered for these latter patients (see Table 25-8).

Angiotensin Receptor Blockers

ARBs are well tolerated in patients who are intolerant of ACE inhibitors because of cough, skin rash, and angioedema and should therefore be used in symptomatic and asymptomatic patients with an EF below 40% who are ACE-intolerant for reasons other than hyperkalemia or renal insufficiency (see [Table 25-9](#)). Although ACE inhibitors and ARBs inhibit the renin-angiotensin system, they do so by a different mechanism: Whereas ACE inhibitors block the enzyme responsible for converting angiotensin I to angiotensin II, ARBs block the effects of angiotensin II on the angiotensin type 1 receptor (see [Chapter 22](#)), the receptor subtype that is responsible for virtually all of the adverse biologic effects relevant to a angiotensin II on cardiac remodeling (see [Chapter 22](#)). Multiple ARBs that are approved for the treatment of hypertension are now available to clinicians. Three of these—losartan, valsartan, and candesartan—have been extensively evaluated in the setting of HF (see [Table 25-9](#)). Several studies have shown modest therapeutic benefit for the addition of ARB to an ACE inhibitor in patients with chronic HF. ARBs should be initiated with the starting doses shown in [Table 25-8](#), which can be uptitrated every 3 to 5 days by doubling the dose of ARB. As with ACE inhibitors, blood pressure, renal function, and potassium should be reassessed within 1 to 2 weeks after initiation and monitored closely after changes in dose.

In patients with symptomatic HF who were intolerant of ACE inhibitors, the aggregate clinical data suggest that ARBs are as effective as ACE inhibitors in reducing HF-related morbidity and mortality.²⁹ Candesartan significantly reduced all-cause mortality, cardiovascular death or hospital admission for CHF in the Candesartan Heart Failure: Assessment of Reduction in Mortality and Morbidity trial (CHARM-Alternative Trial) ([Fig. e25-2](#)).³⁰ Of importance, candesartan reduced all-cause mortality, irrespective of background ACE inhibitor or beta blocker therapy. Similar findings were shown with valsartan in the small subgroup of patients not receiving an ACE inhibitor in the Valsartan Heart Failure Trial (Val-HeFT).³¹ A direct comparison of ACE inhibitor and ARBs was assessed in the Losartan Heart Failure Survival Study (ELITE-II), which showed that losartan was not associated with improved survival in elderly patients with HF when compared with captopril but was significantly better tolerated. Two trials have evaluated ARBs compared with ACE inhibition in post-MI patients in whom LV dysfunction or signs of HF developed during therapy. The direct comparison of losartan with captopril indicated that losartan was not as effective as captopril on all-cause mortality, whereas valsartan was shown to be noninferior to captopril on all-cause mortality in the Valsartan in Acute Myocardial Infarction Trial (VALIANT).³² The combination of captopril and valsartan produced no further reduction in mortality in VALIANT, although the number of adverse events increased. When given in addition to ACE inhibitors in general cohorts of patients with symptomatic HF, the effects of ARBs were shown to have a modest beneficial effect in the CHARM-Added trial³³ ([Fig. e25-2B](#)). However, the addition of valsartan to ACE inhibitors had no beneficial effect on mortality in the Valsartan Heart Failure Trial (Val-HeFT), although the combined endpoint mortality and morbidity was significantly (13.2%) lower with valsartan than with placebo because of a reduction in the number of patients hospitalized for HF.³¹ The question of high-dose versus low-dose angiotensin receptor antagonism in clinical outcomes was evaluated in the Heart Failure Endpoint Evaluation of Angiotensin II Antagonist Losartan (HEAAL) trial.³⁴ This study showed that the use of a high-dose losartan was not associated with a significant reduction in the primary endpoint of all-cause death or hospital admission for HF (HR, 0.94 [95% CI, 0.84 to 1.04]; $P = .24$) when compared with low-dose losartan but was associated with a significant reduction in HF admissions (HR, 0.94 [95% CI, 0.84 to 1.04]; $P = .24$), suggesting that uptitration of ARBs may confer clinical benefit.

Although one meta-analysis suggests that ARBs and ACE inhibitors have similar effects on all-cause mortality and HF-related hospitalizations,³⁵ and although use of ARBs may be considered as initial therapy rather than ACE inhibitors after MI, the general consensus is that ACE inhibitors remain first-line agents for the treatment of HF, whereas ARBs are recommended for ACE-intolerant patients (see also HF guidelines).^{2,14}

Complications of Angiotensin Receptor Blocker Use

Both ACE inhibitors and ARBs have similar effects on blood pressure, renal function, and potassium. Therefore the problems of symptomatic hypotension, azotemia and hyperkalemia will be similar for both of these agents. Although less frequent than with ACE inhibitors, angioedema also has been reported in some patients who receive ARBs. In patients who are intolerant of ACE inhibitors and ARBs, the combined use of hydralazine and isosorbide dinitrate may be considered as a therapeutic option in such patients (see [Table 25-8](#)). Compliance with this combination generally has been poor, however, because of the large number of tablets required and the high incidence of adverse reactions.

Beta Blockers

Beta blocker therapy represents a major advance in the treatment of patients with HFrEF. Beta blockers interfere with the harmful effects of sustained activation of the central nervous system by competitively antagonizing one or more adrenergic receptors (α_1 , β_1 , and β_2). Although a number of potential benefits may be obtained by blocking all three receptors, most of the deleterious effects of sympathetic activation are mediated by the β_1 adrenergic receptor.³⁶ When given in concert with ACE inhibitors, beta blockers reverse the process of LV remodeling, ameliorate patient symptoms, prevent hospitalization, and prolong life. Therefore beta blockers are indicated for patients with symptomatic or asymptomatic HF and a depressed EF to below 40%.

Three beta blockers have been shown to be effective in reducing the risk of death in patients with chronic HF: bisoprolol and sustained-release metoprolol succinate both competitively block the β_1 receptor, and carvedilol competitively blocks the α_1 , β_1 , and β_2 receptors. As with ACE inhibitors, beta blockers should be initiated in low doses (see [Table 25-8](#)), followed by gradual increments in dosing if lower doses have been well tolerated. The dose of beta blocker should be increased until it approximates doses that have been reported to be effective in clinical trials (see [Table 25-8](#)). However, unlike with ACE inhibitors, which may be uptitrated relatively rapidly, the dose titration of beta blockers should proceed no sooner than 2-week intervals, because the initiation and/or increased dosing of these agents may lead to worsening fluid retention consequent to the abrupt withdrawal of adrenergic support to the heart and the circulation. Therefore it is important to optimize the dose of diuretic before therapy with beta blockers is started. If worsening fluid retention does occur, it is likely to appear within 3 to 5 days of initiating therapy and will be manifested as increase in body weight and/or symptoms of worsening HF. The increased fluid retention usually can be managed by increasing the dose of diuretics. Patients need not be taking high doses of ACE inhibitors before being considered for treatment with a beta blocker, because most patients enrolled in the beta blocker trials were not taking high doses of ACE inhibitors. Furthermore, in patients taking a low dose of an ACE inhibitor, the addition of a beta blocker produces greater symptomatic improvement and reduction in the risk of death than does an increase in the dose of the ACE inhibitor. Recent data show that beta blockers can be safely started before discharge even in patients hospitalized for HF, provided that the patient is stable and does not require intravenous HF therapy. Contrary to early reports, the aggregate results of clinical trials suggest that beta blocker therapy is well tolerated by the great majority of patients with HF (>85%), including patients with comorbid conditions such as diabetes mellitus, chronic obstructive lung disease, and peripheral vascular disease. Nonetheless, a subset of patients (10% to 15%) remain intolerant to beta blockers because of worsening fluid retention or symptomatic hypotension.

The first placebo-controlled multicenter trial with a beta-blocking agent was the Metoprolol in Dilated Cardiomyopathy (MDC) trial, which used the shorter-acting tartrate preparation at a target dose of 50 mg three times a day in patients with symptomatic HF with idiopathic dilated cardiomyopathy. Metoprolol tartrate at an average dose of 108 mg/day reduced the prevalence of the primary endpoint of

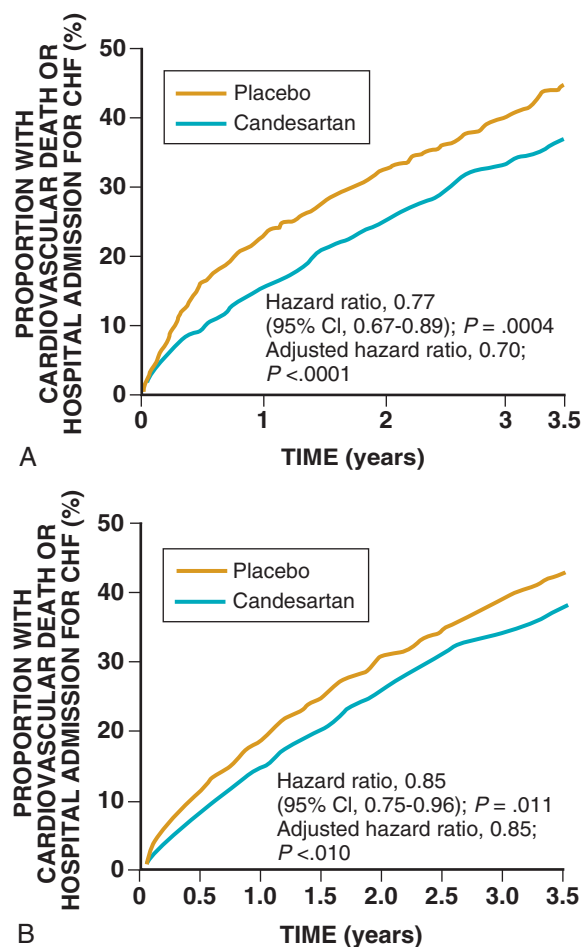

FIGURE e25-2 Effect of candesartan on cardiovascular mortality or hospital admission for HF in the CHARM-Alternative (**A**) trial and the CHARM-Added (**B**) trial. Two groups of patients were randomly assigned to receive candesartan or placebo; in **A**, patients were not receiving an ACE inhibitor, and in **B**, patients were receiving an ACE inhibitor. The effect size of candesartan was reduced in the group of patients who were receiving an ACE inhibitor. (Modified from Granger CB, McMurray JJ, Yusuf S, et al: Effects of candesartan in patients with chronic heart failure and reduced left-ventricular systolic function intolerant to angiotensin-converting-enzyme inhibitors: The CHARM-Alternative trial. *Lancet* 362:772, 2003; and McMurray JJ, Ostergren J, Swedberg K, et al: Effects of candesartan in patients with chronic heart failure and reduced left-ventricular systolic function taking angiotensin-converting-enzyme inhibitors: the CHARM-Added trial. *Lancet* 362:767, 2003.)

death or need for cardiac transplantation by 34%, which did not quite reach statistical significance ($P = .058$). The benefit was due entirely to a reduction by metoprolol in the morbidity component of the primary endpoint, with no favorable trends in the mortality component of the primary endpoint. A more efficacious formulation of metoprolol was subsequently developed, metoprolol (succinate) CR/XL, which has a better pharmacologic profile than metoprolol tartrate because of its controlled-release profile and longer half-life. In the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart risk reduction of 34% reduction in mortality in subjects with mild to moderate HF and moderate to severe systolic dysfunction when compared with the placebo group²⁹ (Fig. 25-16). Of importance, metoprolol CR/XL reduced mortality from both sudden death and progressive pump failure. Furthermore, mortality was reduced across most demographic groups, including older versus younger subjects, non-ischemic versus ischemic etiology, and lower versus higher ejection fractions.

Bisoprolol is a second-generation beta₁ receptor-selective blocking agent with approximately 120-fold higher affinity for human beta₁ versus beta₂ receptors. The first trial performed with bisoprolol was the Cardiac Insufficiency Bisoprolol Study I (CIBIS-I) trial, which examined the effects of bisoprolol on mortality in subjects with symptomatic ischemic or nonischemic cardiomyopathy. CIBIS-I showed a nonsignificant ($P = .22$) 20% risk reduction for mortality at 2-year follow-up evaluation. Because the sample size for CIBIS-I was based on an unrealistically high expected event rate in the control group, a follow-up trial with more conservative effect size estimates and sample size calculations was conducted. In CIBIS-II bisoprolol reduced all-cause mortality by 32% (11.8% versus 17.3%; $P = .002$), sudden cardiac death by 45% (3.6% versus 6.4%; $P = .001$), HF hospitalizations by 30% (11.9% bisoprolol versus 17.6% placebo; $P < .001$), and all-cause hospitalizations by 15% (33.6% versus 39.6%; $P = .002$) (Fig. 25-16B). The CIBIS-III trial addressed the important question of whether an initial treatment strategy using the beta blocker bisoprolol was noninferior to a treatment strategy of using an ACE inhibitor (enalapril) first, among patients with newly diagnosed mild to moderate HF. The two strategies were compared in a blinded manner with regard to the combined primary endpoint of all-cause mortality or hospitalization, as well as with regard to each of the components of the primary endpoint individually. Although the per-protocol primary endpoint analysis of death or rehospitalization did not meet the pre-specified criteria for noninferiority, the intent-to-treat analysis showed that bisoprolol was noninferior to enalapril (HR, 0.94 [95% CI, 0.77 to 1.16]; $P = .019$ for noninferiority). Although CIBIS-III did not provide clear-cut evidence to justify starting with a beta blocker first, the overall safety profile of the two strategies was similar. Current guidelines continue to recommend starting with an ACE inhibitor first, with the subsequent addition of a beta blocker.

Of the three beta blockers that are approved for the treatment of HF, carvedilol has been studied most extensively (see Table 25-9). The phase III U.S. Trials Program, composed of four individual trials managed by a single Steering and Data and Safety Monitoring Committee, was stopped prematurely because of a highly significant ($P < .0001$) 65% reduction in mortality by carvedilol that was observed across all four trials. This was followed by a second study, the Australia-New Zealand Heart Failure Research Collaborative Group Carvedilol Trial (ANZ-Carvedilol), which showed a significant improvement in LVEF ($P < .0001$) and a significant ($P = .0015$) reduction in LV end-diastolic volume index in the carvedilol-treated group at 12 months, as well as a significant relative risk reduction of 26% in the clinical composite of death and hospitalization for the carvedilol group at 19 months. Rates of hospitalization also were significantly lower for patients treated with carvedilol (48%) compared with placebo (58%). The Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) study extended these benefits to patients with more advanced HF. In COPERNICUS, patients with advanced HF symptoms had to be clinically euolemic and have an LV EF less than 25%. When compared with placebo, carvedilol reduced the mortality risk at 12 months by 38% (see Table 25-9) and the relative risk of death or HF hospitalization by 31% (Fig. 25-16C). Carvedilol also has been evaluated in a post-MI trial in which patients had to exhibit LV dysfunction for inclusion. The Carvedilol Post-Infarct Survival Controlled Evaluation (CAPRICORN) trial was a randomized, placebo-controlled study designed to test the long-term effectiveness of carvedilol for reducing morbidity and mortality in patients with LV dysfunction after MI already treated with ACE inhibitors.³⁷ Although carvedilol did not reduce the prespecified primary endpoint of mortality plus cardiovascular hospitalization, it did significantly reduce total mortality by 23% ($P = .03$), cardiovascular

FIGURE 25-16 Kaplan-Meier analysis of the probability of survival among patients in the placebo and beta blocker treatment groups in the MERIT-HF (top), CIBIS II (middle), and COPERNICUS (bottom) trials. CHF = chronic heart failure; CI = confidence interval. (Data from The Cardiac Insufficiency Bisoprolol Study II (CIBIS II): A randomized trial. *Lancet* 353:9, 1999; Metoprolol CR/XL randomized intervention trial in congestive heart failure [MERIT-HF]. *Lancet* 353:2001, 1999; and Packer M, Coats AJ, Fowler MB, et al: Effect of carvedilol on survival in severe chronic heart failure. *N Engl J Med* 344:1651, 2001.)

mortality by 25% ($P < .05$), and nonfatal MI by 41% ($P = .014$). Finally, in the Carvedilol or Metoprolol European Trial (COMET) carvedilol (target dose 25 mg twice daily) was compared with immediate-release metoprolol tartrate (target dose 50 mg twice daily) with respect to the primary endpoint of all-cause mortality. In COMET, carvedilol was

associated with a significant 33% reduction in all-cause mortality when compared with metoprolol tartrate (33.9% versus 39.5%) (HR, 0.83 [95% CI, 0.74 to 0.93]; $P = .0017$).³⁸ On the basis of the results of the COMET study, short-acting metoprolol tartrate is not recommended for use in the treatment of HF. The results of COMET emphasize the importance of using doses and formulations of beta blockers that have been shown to be effective in clinical trials. No trials have been conducted to ascertain whether the survival benefits of carvedilol are greater than those of metoprolol (succinate) CR/XL when both drugs are used at the appropriate target doses.

Not all studies with beta blockers have been universally successful, suggesting that the effects of these drugs should not necessarily be viewed broadly as class effects. Indeed, early studies with the first generation of nonspecific beta₁ and beta₂ receptors without ancillary vasodilating properties (e.g., propranolol) resulted in significant worsening of HF and death. The Beta-Blocker Evaluation of Survival Trial (BEST) evaluated the third-generation beta-adrenergic blocking agent bucindolol, which is a completely nonselective beta₁ and beta₂ blocker with some alpha₁ receptor blockade properties. A nonsignificant ($P = .10$) 10% reduction in total mortality was noted in the bucindolol-treated group, whereas a statistically significant ($P = .01$) 19% reduction in mortality was observed in white patients. This differential response to bucindolol has been suggested to be secondary to a polymorphism (arginine 389) in the beta₁-adrenergic receptor that is more prevalent among whites.

For further discussion on this topic, see the online supplement for this chapter, “Pharmacogenomics.”

Nebivolol is a selective beta₁ receptor antagonist with ancillary vasodilatory properties that are mediated, at least in part, by nitric oxide. In the Study of Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS), nebivolol significantly reduced the composite outcome of death and cardiovascular hospitalizations (HR, 0.86 [95% CI, 0.74 to 0.99]; $P < .04$), which was the primary endpoint of the trial, but did not reduce mortality. Although approximately 35% of the patients in SENIORS had an LVEF greater than 35%; more than half of these patients had an EF ranging from 35% to 50% and therefore would not be considered to have HFpEF. Nebivolol is not FDA-approved for the treatment of HF.

Side Effects of Beta Blockers

The adverse effects of beta blockers generally are related to the predictable complications that arise from interfering with the adrenergic nervous system. These reactions usually occur within several days of initiating therapy and generally are responsive to adjusting concomitant medications as described earlier. The problem of fluid retention has been discussed earlier. Treatment with a beta blocker can be accompanied by feelings of general fatigue or weakness. In most instances, the increased fatigue spontaneously resolves within several weeks or months; however, in some patients, it may be severe enough to limit the dose of beta blocker or require the withdrawal or reduction of treatment. Therapy with beta blockers can lead to bradycardia and/or exacerbate heart block. Moreover, beta blockers (particularly those that block the α₁ receptor) can lead to vasodilatory side effects. Accordingly, the dose of beta blockers should be decreased if the heart rate decreases to less than 50 beats/min and/or if second- or third-degree heart block or symptomatic hypotension develops. Continuation of beta blocker treatment during an episode of acute decompensation is safe, although dose reduction may be necessary.³⁹ Beta blockers are not recommended for patients with asthma with active bronchospasm.

Aldosterone Antagonists

Although classified as a potassium-sparing diuretics, drugs that block the effects of aldosterone (e.g., spironolactone) have beneficial effects that are independent of the effects of these agents on sodium balance (see Fig. 25-11). Although ACE inhibitors may transiently decrease aldosterone secretion, with chronic therapy there is a rapid return of aldosterone to levels similar to those before ACE inhibitor. The administration of an aldosterone antagonist is recommended for

patients with NYHA class II or IV HF who have a depressed EF (<35%), and who are receiving standard therapy including diuretics, ACE inhibitors, and beta blockers.²⁹ The dose of aldosterone antagonist should be increased until the doses used are similar to those that have been shown to be effective in clinical trials (see Table 25-8). Spironolactone should be initiated at a dose of 12.5 to 25 mg daily and uptitrated to 25 to 50 mg daily, whereas eplerenone should be initiated at doses of 25 mg/day and increased to 50 mg/day (see Table 25-9). As noted previously, potassium supplementation generally is stopped after the initiation of aldosterone antagonists, and patients should be counseled to avoid highpotassium-containing foods. Potassium levels and renal function should be rechecked within 3 days and again at 1 week after initiation of an aldosterone antagonist. Subsequent monitoring should be dictated by the general clinical stability of renal function and fluid status but should occur at least monthly for the first 6 months.

The first evidence that aldosterone antagonists could produce a major clinical benefit in HF was demonstrated by the Randomized Aldactone Evaluation Study (RALES) trial,⁴⁰ which evaluated spironolactone (25 mg/day initially, titrated to 50 mg/day for signs of worsening HF) versus placebo in NYHA class III or IV HF patients with an LVEF below 35%, who were being treated with an ACE inhibitor, a loop diuretic, and in most cases digoxin. As shown in Figure 25-11A, administration of spironolactone led to a 30% reduction in total mortality when compared with placebo ($P = .001$). The frequency of hospitalization for worsening HF also was 35% lower in the spironolactone group than in the placebo group. Although the mechanism for the beneficial effect of spironolactone has not been fully elucidated, prevention of extracellular matrix remodeling (see Chapter 22) and prevention of increasing potassium levels are plausible mechanisms. Although spironolactone was well tolerated in RALES, gynecomastia was reported in 10% of men who were treated with spironolactone, as compared with 1% of men in the placebo group ($P < .001$). The Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) trial, which was performed in patients with NYHA class II HF with an EF below 30% (or 35% if the QRS width was more than 130 milliseconds), demonstrated that eplerenone (titrated to 50 mg/day) led to a significant 27% decrease in cardiovascular death or HF hospitalization (HR, 0.63 [95% CI, 0.54 to 0.74]; $P < .001$) (see Fig. 25-11B).⁴¹ Significant decreases also were observed in all-cause death (24%), cardiovascular death (24%), all-cause hospitalization (23%), and HF hospitalizations (43%). Of importance, the effect of eplerenone was consistent across all prespecified subgroups. In contrast with the RALES trial, which was conducted before the widespread adoption of beta blockers, the background therapy for EMPHASIS-HF included ACE inhibitors or ARBs and beta blockers. The findings in RALES and EMPHASIS-HF are consistent with those in randomized clinical trials in patients with acute MI and LV dysfunction. The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival (EPHESUS) study evaluated the effect of eplerenone (titrated to a maximum of 50 mg/day) on morbidity and mortality among patients with acute MI complicated by LV dysfunction and HF. Treatment with eplerenone led to a 15% decrease in all-cause death in the EPHESUS trial (RR, 0.85 [95% CI, 0.75 to 0.96]; $P = .008$). On the basis of the results of the RALES and EMPHASIS-HF trials,⁴⁰ aldosterone antagonists currently are recommended for all patients with persistent NYHA class II to IV symptoms and an EF less than 35%, despite treatment with an ACE inhibitor (or an ARB if an ACE inhibitor is not tolerated) and a beta blocker.

Side Effects of Aldosterone Antagonists

The major problem with the use of aldosterone antagonists is the development of life-threatening hyperkalemia, which is more prone to occur in patients who are receiving potassium supplements or those with underlying renal insufficiency. Aldosterone antagonists are not recommended when the serum creatinine is greater than 2.5 mg/dL (or creatinine clearance is below 30 mL/min) or the serum potassium is greater than 5.5 mmol/liter. The development of worsening renal function should lead to consideration regarding whether to continue aldosterone antagonists because of the associated risk of hyperkalemia. Painful gynecomastia may develop in 10% to 15% of patients who use spironolactone, in which case eplerenone may be substituted.

Ivabradine

Ivabradine is a heart rate–lowering agent that acts by selectively blocking the cardiac pacemaker I_f (“funny”) current that controls the spontaneous diastolic depolarization of the sinoatrial node. Ivabradine blocks I_f channels in a concentration-dependent manner by entering the channel pore from the intracellular side and thus can only block the channel when it is open. The magnitude of I_f inhibition is directly related to the frequency of channel opening and would therefore be expected to be most effective at higher heart rates. Initially developed and approved as an antianginal agent in Europe, ivabradine also was shown to improve outcomes in the Systolic Heart Failure Treatment with the I_f Inhibitor Ivabradine Trial (SHIFT), which enrolled symptomatic patients with an LVEF of 35% or less who were in sinus rhythm with heart rate of 70 beats/min or higher and on standard medical therapy for HF (including beta blockers). SHIFT showed that ivabradine (uptitrated to a maximal dosage of 7.5 mg twice daily) reduced the primary composite outcome of cardiovascular death and HF hospitalization by 18% (HR, 0.82 [95% CI 0.75 to 0.90]; $P < .0001$) (Fig. 25-17). The composite endpoint was driven primarily by reducing hospital admissions for worsening HF (HR, 0.74 [95% CI, 0.66 to 0.83]; $P < .0001$), as indicated by the lack of decrease in cardiovascular deaths (HR, 0.91 [95% CI, 0.80 to 1.03]; $P = .13$) or all-cause death.⁴² Inasmuch as ivabradine lowered heart rate by approximately 10 beats/min and only 26% of the patients in the trial were on optimal doses of beta blockers, it is possible that titrating beta blockers to recommended dose may have reduced the HF hospitalizations to a similar degree. Additional safety evidence for ivabradine comes from the morbidity-mortality evaluation of the I_f inhibitor ivabradine in patients with coronary disease and LV dysfunction (BEAUTIFUL) trial, in which more than 10,000 patients with coronary heart disease and an EF below 40% were randomly assigned to treatment with ivabradine 7.5 mg twice daily or placebo. Although this trial did not meet its primary endpoint of reducing cardiovascular death, MI, or HF hospitalization, the drug was well tolerated in this patient population.⁴³

Renin Inhibitors

Aliskiren is an orally active direct renin inhibitor that appears to suppress the renin-angiotensin system to a similar degree to that effected by ACE inhibitors.⁴⁴ Although the benefits of ACE inhibitors and ARBs in HF have been clearly established, these agents provoke a compensatory increase in renin and downstream intermediaries of the renin-angiotensin-aldosterone system that may attenuate the effects of ACE

inhibitors and ARBs (“RAAS escape”). Aliskiren is a nonpeptide inhibitor that binds to the active site (S1/S3 hydrophobic binding pocket) of renin, preventing the conversion of angiotensinogen to angiotensin I (see Fig. 22-4), and was shown to significantly ($P < .01$) decrease NT-proBNP in urinary aldosterone excretion, in the Aliskiren Observation of Heart Failure Treatment (ALOFT) trial.⁴⁵ On the basis of these promising early results, several large pivotal outcomes trials were initiated to determine whether adding aliskiren to standard HF therapy would improve clinical outcomes. The Aliskiren Trial on Acute Heart Failure Outcomes (ASTRONAUT) enrolled patients with an LVEF of 40% or less and elevated natriuretic peptide (BNP) of 400 pg/mL or higher or NT-proBNP of 1600 pg/mL or greater) who were being discharged from the hospital after admission for an acute decompensated HF.⁴⁶ The primary endpoint of ASTRONAUT was cardiovascular death or HF rehospitalization at 6 months. No significant difference in the primary endpoint was observed in the aliskiren (titrated up to 300 mg/day)-treated group compared with patients treated with standard medical therapy for HF at 6 months (HR, 0.92 [95% CI, 0.76 to 1.12]; $P = .41$) or at 12 months (HR, 0.93 [95% CI, 0.79 to 1.09]; $P = .36$). Moreover, the rates of hyperkalemia, hypotension, and renal impairment/renal failure were higher in the aliskiren group than in the placebo group. Aliskiren currently is being evaluated in a phase III study that will evaluate the efficacy and safety of both aliskiren monotherapy and aliskiren-enalapril combination therapy as compared with enalapril monotherapy to reduce cardiovascular death and HF-related hospitalizations in NYHA class II to IV HF patients in the ATMOSPHERE (Efficacy and Safety of Aliskiren and Aliskiren/Enalapril Combination on Morbi-mortality in Patients with Chronic Heart Failure) study (ClinicalTrials.gov Identifier: NCT00853658).

PHARMACOGENOMICS

As discussed in Chapter 9, the field pharmacogenetics attempts to define common gene polymorphisms, or sets of polymorphisms, that underlie variability in drug action. In view of the tremendous heterogeneity observed among in patients with HF, it is likely that genetic variations play a significant role in determining drug metabolism, disposition, and functional activity in these patients. Recent advances in the field of pharmacogenetics suggest an analysis of underlying gene polymorphism in disease causing pathways may one day enable clinicians to develop personalized therapeutic regimens for patients with HF. In view of the central role of the renin-angiotensin-aldosterone and adrenergic systems in the pathophysiology (see Chapter 22) and treatment of HF, it is perhaps not surprising that polymorphisms in the genes that regulate these pathways appear to influence the therapeutic efficacy of ACE inhibitors and/or beta blockers.

An overview of the major genetic variations in these pathways and the proposed functional impact of these polymorphisms, with a description of how these genetic polymorphisms influence traditional pharmacotherapeutic approaches in HF, is available in an online supplement for this chapter (“Pharmacogenomics”).

FIGURE 25-17 Kaplan-Meier cumulative event curves for the primary composite endpoint of cardiovascular death and hospitalization for worsening HF in patients treated with ivabradine compared with those receiving placebo. (Modified from Swedberg K, Komajda M, Bohm M, et al: Ivabradine and outcomes in chronic heart failure (SHIFT): A randomised placebo-controlled study. *Lancet* 376:875, 2010.)

MANAGEMENT OF PATIENTS WHO REMAIN SYMPTOMATIC

Background Therapy

As noted, an ACE inhibitor (or an ARB) plus a beta blocker should be standard background therapy for patients with HFrEF. Additional pharmacologic therapy (polypharmacy) or device therapy (see further on) should be considered in patients who have persistent symptoms or progressive worsening despite optimized therapy with an ACE inhibitor and beta blocker (Fig. 25-18; see also Table 25-9). Agents that may be considered for part of additional therapy include an ARB (NYHA class II to IV), mineralocorticoid receptor antagonists (NYHA class II to IV), the combination of hydralazine and isosorbide

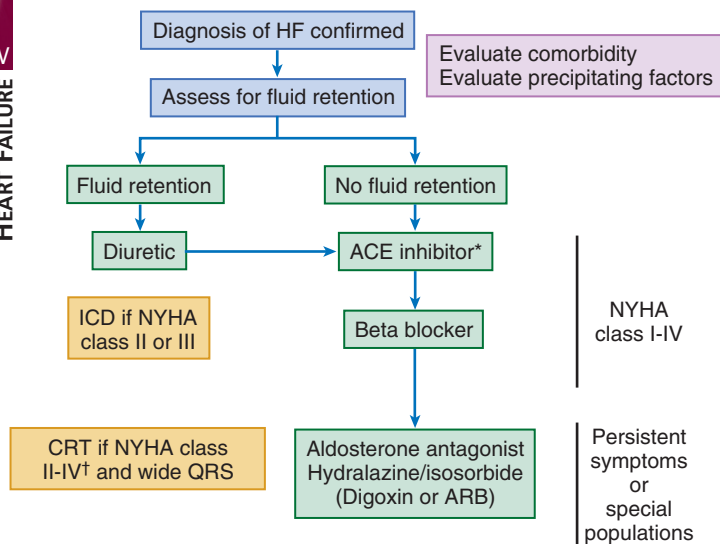

FIGURE 25-18 Treatment algorithm for chronic HF in patients with a reduced EF. After the clinical diagnosis of HF is made, it is important to treat the patient's fluid retention before initiation of an ACE inhibitor (or an ARB if the patient is ACE inhibitor-intolerant). Beta blockers should be started after the fluid retention has been treated and/or the ACE inhibitor has been uptitrated. If the patient remains symptomatic, an aldosterone antagonist can be added for "triple therapy." The fixed-dose combination of hydralazine plus isosorbide dinitrate should be added to an ACE inhibitor and beta blocker in African American patients with NYHA class II to IV HF. ARBs also can be added in patients who remain symptomatic and are intolerant of aldosterone antagonists. Digoxin also can be added if patients remain symptomatic despite triple therapy. Device therapy should be considered as an addition to pharmacologic therapy in appropriate patients (see Table 25-1). *ARB if ACE-intolerant. †CRT may be indicated in NYHA class I HF patients with an left bundle branch block (LBBB) pattern on the electrocardiogram (ECG), LVEF below 30%, and QRS width greater than 150 milliseconds. (Modified from Mann DL: *Heart failure and cor pulmonale*. In Kasper DL, Braunwald E, Fauci AS, et al [eds]: *Harrison's Principles of Internal Medicine*. 17th ed. New York, McGraw-Hill, 2007, p 1450.)

dinitrate (NYHA class II to IV) or digitalis.²⁹ Thus the choice of specific agent will be influenced in part by clinical considerations, including renal function, serum potassium concentration, blood pressure, and race (see below). Because mineralocorticoid receptor antagonists have a greater impact on morbidity/mortality than ARBs, ARBs are no longer the agents of first choice in patients with HF and an EF of 40% or less who remain symptomatic despite optimal treatment with an ACE inhibitor. The triple combination of an ACE inhibitor, an ARB, and an aldosterone antagonist is not recommended because of the associated risk of hyperkalemia. Digoxin is recommended for patients with symptomatic LV systolic dysfunction who have concomitant atrial fibrillation and should be considered for patients who have signs or symptoms of HF while receiving standard therapy, including ACE inhibitors and beta blockers.

Cardiac Glycosides

Digoxin and digitoxin are the most frequently used cardiac glycosides. Because digoxin is the most commonly used and is the only glycoside that has been evaluated in placebo-controlled trials, little reason exists to prescribe other cardiac glycosides for the management of patients with chronic HF. Digoxin exerts its effects by inhibiting the sodium potassium adenosine triphosphate (Na^+/K^+ -ATPase) pump in cell membranes, including the sarcolemmal Na^+/K^+ -ATPase pump of cardiac myocytes (see Chapter 22). Inhibition of the Na^+/K^+ -ATPase pump leads to an increase in intracellular calcium and hence increased cardiac contractility, suggesting that beneficial effects of digoxin might be secondary to its inotropic properties. However, the more likely mechanism of action for digoxin in patients with HF is to sensitize Na^+/K^+ -ATPase activity in vagal afferent nerves, leading to an increase in vagal tone that counterbalances the increased activation of the adrenergic system in advanced HF. Digoxin also inhibits Na^+/K^+ -ATPase activity in the kidney and may, therefore, blunt renal

tubular resorption of sodium. Therapy with digoxin commonly is initiated and maintained at a dose of 0.125 to 0.25 mg daily. For the great majority of patients, the dose should be 0.125 mg daily and the serum digoxin level should be below 1.0 ng/mL, especially in elderly patients, patients with impaired renal function, and patients with a low (lean) body mass. Higher doses (e.g., digoxin > 0.25 mg daily) are rarely used and are not recommended for the management of patients with HF who are in sinus rhythm or who have atrial fibrillation.

Additional content on this topic, including details about the mechanism of action, pharmacokinetics, and interaction of digitalis with other commonly used drugs, is available in an online supplement for this chapter ("Cardiac Glycosides").

Although clinicians have used cardiac glycosides to treat patients with chronic HF for well over 200 years, considerable debate continues regarding the effectiveness of these agents in patients with HF. Whereas small and medium-sized trials conducted in the 1970s and 1980s yielded equivocal results, two relatively large digoxin withdrawal studies in the early 1990s, the Randomized Assessment of Digoxin and Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) and the Prospective Randomized Study of Ventricular Function and Efficacy of Digoxin (PROVED), provided strong support for clinical benefit of digoxin.⁴⁷ In these studies, worsening HF and increased HF hospitalizations were more common among patients who were withdrawn from digoxin than among those who were maintained on digoxin. Because withdrawal studies are difficult to interpret with respect to efficacy of a given therapeutic agent, the Digoxin Investigator Group (DIG) trial was conducted to prospectively address the role of digitalis in chronic HF. Although the DIG trial showed that digoxin had a neutral effect on the primary endpoint of mortality, digoxin reduced hospitalizations (including 30-day readmissions for HF)⁴⁸ and favorably affected the combined endpoints of death and hospitalization for worsening HF. Data from the DIG trial indicated a strong trend ($P = .06$) toward a decrease in deaths secondary to progressive pump failure, which was offset by an increase in sudden and other non-pump failure cardiac deaths ($P = .04$). One of the most important findings to emerge from the DIG trial was that mortality was directly related to the digoxin serum level.¹⁴ In men enrolled in the DIG trial, trough levels between 0.6 and 0.8 ng/mL were associated with decreased mortality, suggesting that trough levels of digitalis should be maintained between 0.5 and 1.0 ng/mL. There is also evidence that digoxin may be potentially harmful in women. In a post hoc multivariable analysis of the DIG trial, digoxin was associated with a significantly higher risk (23%) of death from any cause among women, but not men, possibly because of the relatively lower body weights in women, who were prescribed doses of digoxin on the basis of a nomogram rather than on trough levels.¹⁴ The DIG trial was conducted before the widespread use of beta blockers, and no large trial of digoxin in addition to therapy with both ACE inhibitors and beta blockers is available.

Complications of Digoxin Use

The principal adverse effects of digoxin are (1) cardiac arrhythmias including heart block (especially in the elderly) and ectopic and reentrant cardiac rhythms; (2) neurologic complaints such as visual disturbances, disorientation, and confusion; and (3) gastrointestinal symptoms such as anorexia, nausea, and vomiting. As noted previously, these side effects generally can be minimized by maintaining trough levels of 0.5 to 1.0 ng/mL. In patients with HF, overt digitalis toxicity tends to emerge at serum concentrations that are greater than 2.0 ng/mL; however, digitalis toxicity may occur with lower digoxin levels, particularly if hypokalemia or hypomagnesemia coexist. Oral potassium administration is often useful for atrial, atrioventricular junctional, or ventricular ectopic rhythms, even when the serum potassium is in the normal range, unless high-grade atrioventricular block also is present. However, serum K^+ levels must be monitored carefully to avoid hyperkalemia, especially in patients with renal failure or taking aldosterone receptor antagonists. Potentially life-threatening digoxin toxicity can be reversed by antidigoxin immunotherapy using purified Fab fragments (see the online supplement for this chapter on "Cardiac Glycosides"). The concomitant use of quinidine, verapamil, spironolactone, flecainide, propafenone, and

amiodarone can increase serum digoxin levels and may increase the risk of adverse reactions (see the online supplement “Cardiac Glycosides”). Patients with advanced heart block should not receive the digitalis unless a pacemaker is in place.

n-3 Polyunsaturated Fatty Acids

A large body of experimental evidence suggests that n-3 polyunsaturated fatty acids (n-3 PUFAs) have favorable effects on inflammation, including a reduction in endothelial activation and production of inflammatory cytokines, platelet aggregation, autonomic tone, blood pressure, heart rate, and LV function. The GISSI-HF (Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiaca Heart Failure) showed that long-term administration of 1 g/day of omega n-3 PUFAs resulted in a significant reduction in both all-cause mortality (adjusted HR, 0.91 [95.5% CI, 0.83 to 0.99]; $P = .041$) and all-cause mortality and cardiovascular admissions (adjusted HR, 0.92 [99% CI, 0.849 to 0.999]; $P = .009$), in all of the predefined subgroups, including patients with HF associated with nonischemic cardiomyopathy.⁴⁹ However, in view of the small treatment effect of n-3 PUFAs, they are not endorsed by current practice guidelines.

MANAGEMENT OF ATHEROSCLEROTIC DISEASE

The clinical evaluation of atherosclerotic cardiovascular heart disease in patients with HF is discussed in [Chapter 23](#). In patients with a previous MI and HF without angina, the use of ACE inhibitors and beta blockers has been shown to decrease the risk of reinfarction and death. Although the role of aspirin in patients with HF of ischemic etiology has not been clearly established in randomized trials and remains controversial because of the concern that aspirin may attenuate the beneficial effects of ACE inhibitors, long-term treatment with antiplatelet agents, including aspirin (75 to 81 mg), is recommended for patients with HF of ischemic etiology, regardless of whether they are receiving ACE inhibitors.¹⁴ Alternative antiplatelet agents (e.g., clopidogrel) may not interact adversely with ACE inhibitors and may have superior effects in preventing clinical events; however, a favorable effect on outcomes in HF has not been demonstrated. Coronary artery bypass grafting (CABG) has not been shown to improve cardiac function or to relieve symptoms, or to prevent reinfarction or death in patients with HF without angina. By contrast, CABG has been shown to ameliorate symptoms and improve survival in patients with modestly reduced EF and angina, although patients with clinical HF or markedly depressed ventricular function have generally been excluded from most studies. The recently completed STICH (Surgical Treatment for Ischemic Heart Failure) trial showed that CABG did not reduce all-cause death (HR, 0.86 [95% CI, 0.7 to 1.04]; $P = .12$), which was the primary endpoint of the trial (see [Fig. 28-2](#)), but did reduce a composite endpoint of cardiovascular death, death from any cause, and hospitalization for cardiovascular causes (HR for CABG, 0.74 [95% CI, 0.64 to 0.85]; $P < .001$), which was a prespecified secondary analysis (see [Fig. 28-3](#)). The results of STICH suggest that CABG is beneficial in patients with HF of ischemic etiology who are otherwise suitable candidates for surgery. Although the data are less robust, percutaneous coronary intervention may be considered as an alternative to CABG in patients in whom surgery is not a good option. The surgical management of patients with CAD and HF is discussed in [Chapter 28](#).

SPECIAL POPULATIONS

Women

Although women account for a significant proportion of the growing HF epidemic, they have been poorly represented in clinical trials. Women with HF are more likely to be older (see [Fig. 25-1](#)), have a preserved EF (see [Chapter 27](#)) and nonischemic etiology for their

HF (see also [Chapter 77](#)). Although some studies have reported that HF outcomes are worse for women with than for men, the aggregate data suggest that women have a survival advantage when they develop HF. Although the explanation for this observation is unclear it may be related to sex differences in etiology for HF. Nonetheless, although women appear to have a survival advantage after the diagnosis of HF, they experience increased morbidity, with worse quality of life, and have increased depression. Moreover, women are at increased risk of developing HF after acute MI.⁵⁰ Pooled analysis of several large-scale prospective clinical trials with beta blockers and ACE inhibitors suggests that these agents provide similar survival benefits in women with systolic dysfunction and in men.⁵⁰

Race/Ethnicity

Epidemiologic and clinical trial data have raised awareness of potential areas of concern regarding the evaluation and treatment of HF in specific racial and ethnic groups (see earlier under Epidemiology). The effectiveness of pharmacologic treatments in such subgroups is somewhat controversial, because so few randomized clinical trials of HF treatment that prespecified a subgroup analysis of outcomes stratified by race or ethnicity, with sufficient numbers of subjects for meaningful statistical analysis, have been conducted. Several retrospective analyses have highlighted differences between African American and white populations in response to some standard HF therapies. Unfortunately, data for Hispanic and Asian HF populations are limited. Retrospective analyses from SOLVD and the Vasodilator in Heart Failure Trial (V-HeFT) trials suggested that African Americans do not benefit from ACE inhibitors. By contrast, post hoc analysis of studies with approved beta blockers has shown that African American patients benefit, although the magnitude of the effect appears to be diminished relative to Caucasians.⁵¹ The African-American Heart Failure Trial (A-HeFT) compared the adjunctive use of a proprietary formulation of isosorbide dinitrate and hydralazine against a standard HF regimen of ACE inhibitors, beta blockers, and diuretics in African Americans with NYHA class III or IV HF.⁵² The primary endpoint was a composite score made up of weighted values for death from any cause, a first hospitalization for HF, and change in the quality of life. The study was terminated early because of a significant 43% reduction in the rate of death from any cause (see [Fig. e25-3](#)) and a significant 33% relative reduction in the rate of first hospitalization for HF. The mechanism for the beneficial effect of the hydralazine-isosorbide regimen may be related to an improvement in nitric oxide bioavailability; however, the combination therapy group also demonstrated a small (but significant) effect on blood pressure lowering. The effect of this combination of isosorbide dinitrate and hydralazine in other patients with HF who are being treated with standard therapy is not known, because the population studied in A-HeFT was limited to African Americans. However, there is no reason to believe that this benefit is limited to blacks. The results of the A-HeFT trial have led to the suggestion that the addition of isosorbide dinitrate and hydralazine to a standard medical regimen for HF, including ACE inhibitors and beta blockers, is reasonable and can be effective in African Americans with NYHA functional class III or IV HF ([Fig. 25-18](#)). The emerging field of genomic medicine has begun to suggest that important variances in the expression of certain high-risk, single-nucleotide polymorphisms along racial lines may be evident, providing a physiologic basis for differences in the natural history of HF and differences in drug responsiveness.

Elderly Persons

As noted at the outset, the prevalence of HF increases with age (see [Fig. 25-1](#)) and is the most common reason for hospitalization in elderly patients (see [Chapter 76](#)). Of note, the presentation of HF may differ in elderly patients with HF. Although they commonly present with the classic symptoms of dyspnea and fatigue, elderly patients are more likely than younger patients to present with atypical symptoms such as altered mental status, depression, or poor executive functioning.⁹ The therapeutic approach to HFrEF in elderly

FIGURE e25-3 Kaplan-Meier analysis of the probability of survival among patients in the placebo and isosorbide dinitrate plus hydralazine treatment arms of the A-HeFT study. (Modified from Taylor AL, Ziesche S, Yancy C, et al: Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. *N Engl J Med* 351:2049, 2004.)

persons should be, in principle, identical to that in younger patients with respect to the choice of pharmacologic therapy. However, altered pharmacokinetic and pharmacodynamic properties of cardiovascular drugs in the elderly may require that these therapies be applied more cautiously, with reductions in drug dosages when appropriate (see also Chapter 76). Other complicating factors may include blunting of baroreceptor function and orthostatic dysregulation of blood pressure, which may make it difficult to use target doses of some neurohormonal antagonists. Multidisciplinary HF programs have been successful in decreasing the rate of readmission and associated morbidity in elderly patients (see discussion of Disease Management further on).

Patients with Cancer

Patients with cancer are particularly predisposed to the development of HF as a result of the cardiotoxic effects of many cancer chemotherapeutic agents. The management of these patients is discussed in Chapter 69.

ANTICOAGULATION AND ANTIPLATELET THERAPY

Patients with HF have an increased risk for arterial or venous thromboembolic events. In clinical HF trials the rate of stroke ranges from 1.3%/year to 2.4%/year. Depressed LV function is believed to promote relative stasis of blood in dilated cardiac chambers with increased risk of thrombus formation. Thromboembolism prophylaxis in patients with HF and atrial fibrillation should be individualized and based on an assessment of the risk of stroke versus the risk of bleeding on an anticoagulant. In general most patients with HF with a reduced ejection fraction will have an increased risk of stroke, as assessed by a variety of risk scores (e.g., cardiac failure, hypertension, age ≥ 75 [doubled], diabetes, stroke [doubled]—vascular disease, age 65 to 74/sex [female] [CHA2DS2-VASc]) (see Chapter 38), and treatment with warfarin (international normalized ratio [INR] goal, 2.0 to 3.0) is appropriate. Treatment with warfarin also is recommended for all patients with a history of systemic or pulmonary emboli, including stroke or transient ischemic attack. Patients with symptomatic or asymptomatic ischemic cardiomyopathy and documented recent large anterior MI or recent MI with documented LV thrombus should be treated with warfarin (goal INR, 2.0 to 3.0) for the initial 3 months after MI in the absence of contraindications. The question of whether patients with HF who are in sinus rhythm should be treated with anticoagulants to reduce stroke was addressed in the WARCEF (Warfarin Versus Aspirin in Reduced Cardiac Ejection Fraction) trial, which showed that treatment with warfarin as compared with aspirin did not reduce the composite outcome of time to ischemic stroke, intracerebral hemorrhage, and death from any cause (HR, 0.93 [95% CI, 0.79 to 1.10]; $P = .40$).⁵³ Although treatment with warfarin was associated with a significant reduction in the rate of ischemic stroke (HR, 0.52 [95% CI, 0.33 to 0.82]; $P = .005$), this benefit was offset by a significant increase in the rate of major hemorrhage. Of interest, the rates of intracerebral and intracranial hemorrhage did not differ significantly between the two treatment groups. Based on the results of the WARCEF trial, there is no compelling reason to use warfarin rather than aspirin in patients with HF who are in sinus rhythm.

MANAGEMENT OF CARDIAC ARRHYTHMIAS

Atrial fibrillation is the most common arrhythmia in HF (see also Chapters 37 and 38), and occurs in 15% to 30% of patients. Atrial fibrillation may lead to worsening HF symptoms (see Table 25-6) and increases the risk of thromboembolic complications, particularly stroke. In patients with chronic HF and a history of atrial fibrillation, a strategy of rhythm control (pharmacologic or electrical cardioversion) was not shown to be superior to a strategy of controlling ventricular rate with respect to reducing death from cardiovascular causes (HR rhythm control group, 1.06 [95% CI, 0.86 to 1.30]; $P =$

.59).⁵⁴ Secondary outcomes also were similar in the rate and rhythm control groups, including death from any cause, stroke, worsening HF, and the composite of death from cardiovascular causes, stroke, and worsening HF.⁵⁴ Accordingly, a rhythm control strategy is best suited for use in patients with a reversible secondary cause of atrial fibrillation, or in patients who cannot tolerate symptoms of atrial fibrillation after optimization of rate control and HF therapy. For control of heart rate in patients with HF and atrial fibrillation, beta blockers are preferred over digoxin, inasmuch as digoxin does not provide rate control during exercise. Moreover, beta blockers have favorable effects on mortality and morbidity. Of importance, the combination of digoxin and a beta blocker is more effective than a beta blocker alone in controlling the ventricular rate at rest. When beta-adrenergic blocking agents cannot be used, amiodarone has been recommended by some clinicians, but chronic use has potentially significant risks, including thyroid disease and lung toxicity (see further on). The short-term intravenous administration of diltiazem or amiodarone has been used for the acute treatment of patients with atrial fibrillation with very rapid ventricular response; however, the negative inotropic effects of nondihydropyridine calcium channel blockers such as diltiazem and verapamil must be considered if these agents are used. The optimum control of ventricular rate in patients with HF and atrial fibrillation is unclear at present. Although a resting ventricular response of 60 to 80 beats/min and a ventricular response between 90 and 115 beats/min during moderate exercise has been suggested by some experts, the AF-CHF (Atrial Fibrillation and Congestive Heart Failure) study did not show a difference in a composite of clinical outcomes when a strategy of strict rate control (<80 beats/min at rest and <110 beats/min during a 6-minute walk) was compared with lenient rate control.⁵⁵ With the recognition that sustained tachycardia can lead to a cardiomyopathy, atrioventricular node ablation and cardiac resynchronization therapy (CRT) have been suggested for control of ventricular rate in extreme cases of a rapid ventricular response with atrial fibrillation.²

Most antiarrhythmic agents, with the exception of amiodarone and dofetilide, have negative inotropic effects and are proarrhythmic. Amiodarone is a class III antiarrhythmic that has little or no negative inotropic and/or proarrhythmic effects and is effective against most supraventricular arrhythmias (see also Chapter 38). Amiodarone is the preferred drug for treatment to restore and maintain sinus rhythm and may improve the success of electrical cardioversion in patients with HF. Amiodarone increases the level of phenytoin and digoxin and will prolong the INR in patients taking warfarin. Therefore it often is necessary to reduce the dose of these drugs by as much as 50% on initiation of therapy with amiodarone. The risk of adverse events, such as hyperthyroidism, hypothyroidism, pulmonary fibrosis, and hepatitis, is relatively low, particularly when lower doses of amiodarone are used (100 to 200 mg/day). Dronedarone is a novel antiarrhythmic drug that reduces the incidence of atrial fibrillation and atrial flutter and has electrophysiologic properties that are similar to those of amiodarone but does not contain iodine, with the attendant risk of iodine-related adverse reactions. Although dronedarone was significantly more effective than placebo in maintaining sinus rhythm in several studies, the ANDROMEDA trial (European Trial of Dronedarone in Moderate to Severe Congestive Heart Failure) had to be terminated prematurely because of a twofold increase in mortality (HR ratio, 2.13 [95% CI, 1.07 to 4.25]; $P = .167$) in the dronedarone-treated patients with HF.⁵⁶ The excess mortality was predominantly related to worsening of HF. As a result of this study, dronedarone is contraindicated in patients with NYHA class IV HF, or those with NYHA class II or III HF who have had a recent episode of HF-related decompensation. Because of the increased likelihood of proarrhythmic effects of antiarrhythmic agents in patients with LV dysfunction, it is preferable to treat ventricular arrhythmias with implantable cardioverter-defibrillators (ICDs), either alone or in combination with amiodarone (see also Chapter 26).

DEVICE THERAPY

Cardiac Resynchronization

CRT is discussed in detail in Chapters 26 and 36. When CRT is added to optimal medical therapy in patients in sinus rhythm,

a significant decrease in patient mortality and hospitalization is achieved, along with a reversal of LV remodeling, as well as improved quality of life and exercise capacity (see Chapter 26).⁵⁷

CRT should be considered for patients with NYHA class II to IV HF with depressed EF to below 30% to 35% and a wide QRS (see Table 25-5 for details) who have been on optimal background therapy including an ACE inhibitor/ARB, a beta blocker, and an aldosterone antagonist for several months (see Fig. 25-18) and may be considered in select patients with NYHA class I HF with a wide QRS (see Table 25-5). For eligible patients, consideration should be given for implantation of CRT with an ICD (CRT-ICD).

Implantable Cardioverter Defibrillators

ICDs are discussed in detail in Chapters 26, 36, and 39. Briefly stated, the prophylactic implantation of ICDs in patients with mild to moderate HF (NYHA class II or III) has been shown to reduce the incidence of sudden cardiac death in patients with ischemic or non-ischemic cardiomyopathy (see Chapters 26 and 39). Accordingly, implantation of an ICD should be considered for patients NYHA class II or III HF with a depressed EF to less than 30% to 35% who are already on optimal background therapy including an ACE inhibitor/ARB, a beta blocker, and an aldosterone antagonist for several months, and who have a reasonable expectation of survival with a good functional status for longer than 1 year (see Fig. 25-18). CRT-ICD should be considered for NYHA class IV HF patients.

SLEEP-DISORDERED BREATHING

The general topic of sleep disorders in cardiovascular disease is discussed in detail in Chapter 75. Patients with HFrEF (EF < 40%) commonly exhibit sleep-disordered breathing: Approximately 40% of

patients exhibit central sleep apneas (CSAs), commonly referred to as Cheyne-Stokes breathing (see also Chapter 23), and another 10% exhibit obstructive sleep apneas (OSA). CSA associated with Cheyne-Stokes respiration is a form of periodic breathing, in which central apneas and hypopneas alternate with periods of hyperventilation that exhibit a waxing-waning pattern of tidal volume. Risk factors for the development of CSA in patients with HF include male sex, age older than 60 years, the presence of atrial fibrillation, and hypocapnia.⁵⁸ Figure 25-19 illustrates the proposed mechanisms that underlie periodic oscillations in ventilation in HF, including heightened sensitivity to arterial partial pressure and long circulation time. The main clinical significance of CSA in HF is its association with increased mortality. Whether this is simply because Cheyne-Stokes respiration with CSA is a reflection of advanced disease with poor LV function, or whether its presence constitutes a separate and additive adverse influence on outcomes, is not clear. This statement notwithstanding, multivariate analyses suggest that CSA remains an independent risk factor for death or cardiac transplantation, even after controlling for potentially confounding risk factors. The potential mechanism(s) for adverse outcomes in patients with HF and CSA may be attributed to marked neurohumoral activation (especially norepinephrine). Studies have suggested that Cheyne-Stokes respirations can resolve with proper treatment of HF. However, if the patient continues to have symptoms related to sleep-disordered breathing (sleep-onset or sleep-maintenance insomnia) despite optimization of HF therapies (see Fig. 25-19), a comprehensive overnight sleep study-polysomnography is indicated.

Although current guidelines recommend continuous positive airway pressure (CPAP) therapy to improve functional capacity and quality of life in patients with HF associated with obstructive sleep apnea, no consensus has emerged regarding how CSA should be treated in these patients. Because CSA is to some extent a manifestation of advanced

FIGURE 25-19 Pathophysiology of CSA and Cheyne-Stokes respiration in HF. HF leads to increased LV filling pressure. The resulting pulmonary congestion activates lung vagal irritant receptors, which stimulate hyperventilation and hypocapnia. Superimposed arousals cause further abrupt increases in ventilation and drive the arterial partial pressure of carbon dioxide (PaCO_2) below the threshold for ventilation, triggering central apnea. CSAs are sustained by recurrent arousal resulting from apnea-induced hypoxia and the increased effort to breathe during the ventilatory phase secondary to pulmonary congestion and reduced lung compliance. Increased sympathetic activity causes increases in blood pressure (BP) and heart rate (HR) and increases myocardial O_2 demand in the presence of reduced supply. PaO_2 = partial pressure of oxygen in arterial blood; SNA = sympathetic nervous system activity. (Redrawn from Bradley TD, Floras JS: Sleep apnea and heart failure. Part II: Central sleep apnea. *Circulation* 107:1822, 2003.)

HF, the first consideration is to optimize drug therapy, including aggressive diuresis to lower cardiac filling pressure, along with the use of ACE inhibitors/ARBs and beta blockers, which may lessen the severity of CSA. In some cases, however, metabolic alkalosis arising from diuretic use may predispose the patient to CSA by narrowing the difference between the circulating PaCO_2 level and the PaCO_2 threshold that is necessary for apnea to develop. The use of nocturnal oxygen and devices that provide continuous positive airway pressure has been reported to alleviate CSA, abolish apnea-related hypoxia, and decrease nocturnal norepinephrine levels, as well as to produce symptomatic and functional improvement in patients with HF when used in the short term (for up to 1 month). However, the effects of supplemental oxygen on cardiovascular endpoints over more prolonged periods have not been assessed. Although no direct evidence for prevention of HF by treatment of sleep-disturbed breathing is lacking, treatment with CPAP breathing has been shown to improve LV structure and function in patients with either obstructive or central sleep apnea disturbed-breathing syndrome.⁵⁸ Despite these objective measurements of improvement with CPAP, this treatment modality did not lead to prolongation of life in the Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure (CANPAP) trial,⁵⁸ which was discontinued early after concerns about the early divergence of transplantation-free survival favoring the control group. There was no difference in the primary endpoint of death or transplantation ($P = .54$), nor was there a significant difference in the frequency of hospitalization between groups (0.56 versus 0.61 hospitalization/patient-year; $P = .45$). A post hoc analysis of the CANPAP study, however, suggested that adequate suppression of CSA by CPAP was associated with improved heart transplant-free survival.⁵⁸ Thus the data remain unclear whether elimination of apnea will lead to improved clinical outcomes. The other therapies that have been proposed for sleep-disordered breathing in HF include nocturnal oxygen, CO_2 administration (by adding dead space), theophylline, acetazolamide and diaphragmatic pacing; these interventions have not yet been systematically studied in outcome-based prospective randomized trials (see Chapter 75).⁵⁸

DISEASE MANAGEMENT APPROACH

Despite the compelling scientific evidence that ACE inhibitors/ARBs, beta blockers, and aldosterone antagonists reduce hospitalizations and deaths in patients with HF, these life-prolonging therapies continue to be underused outside of the highly artificial environment of clinical trials. Indeed, numerous studies in a variety of different clinical settings have documented that a significant proportion of patients with HF are not receiving treatment with guideline-recommended, evidence-based therapies.¹⁴ The failure to deliver optimal medical care to patients with HF is almost certainly multifactorial, as it is with other complex chronic conditions that carry substantial morbidity and mortality. Furthermore, the advanced age of many of these patients, who often have myriad comorbid conditions, also presents a special challenge to health care providers. Optimal HF care includes a trained network of health care providers involved in the delivery of HF management and interventions, including nurses, case managers, physicians, pharmacists, case workers, dietitians, physical therapists, psychologists, and information systems specialists; a method for communicating this knowledge to the patient, including patient education, education of caregivers and family members, medication management, peer support, or some form of postacute care, along with a method of ensuring that the patient has received and understood the knowledge; a system for encouraging adherence to the recommended regimen; and patient compliance. Numerous studies have shown that many of the challenges to delivering optimal care

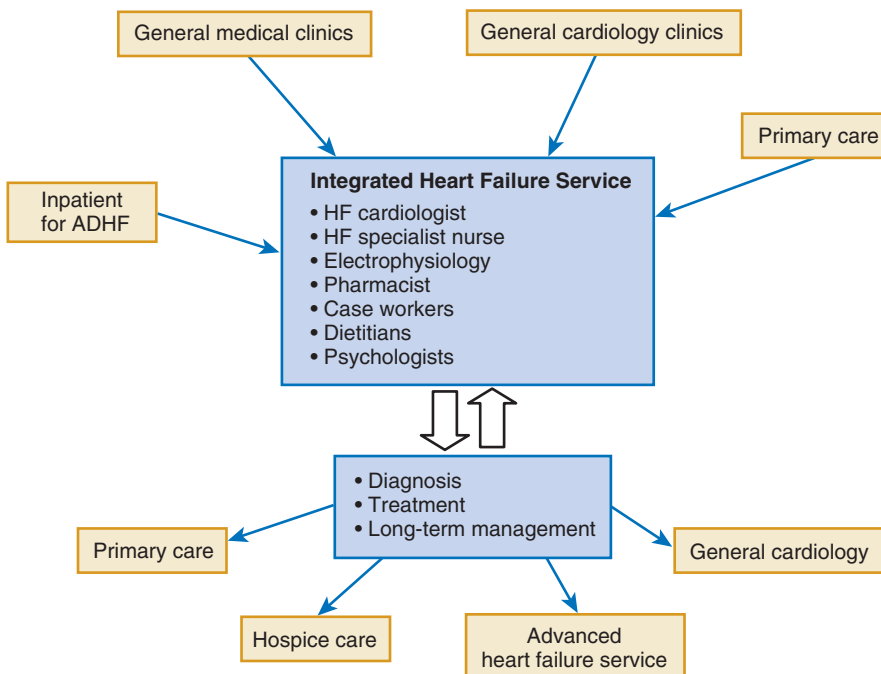

FIGURE 25-20 Integrated disease management program in HF. ADHF = acute decompensated heart failure. (Modified from McDonagh TA: *Lessons from the management of chronic heart failure*. *Heart* 91(Suppl 2):ii24, 2005.)

to patients with HF can be met through an integrated specialized HF clinic approach that uses nurse and physician extenders to deliver and ensure the implementation of care (Fig. 25-20). Technology-driven strategies that use low-cost telemonitoring also appear promising in terms of improving HF management and outcomes (see Chapter 26).⁵⁹ The optimal approach to noninvasive remote monitoring is uncertain, however, and the data from randomized clinical trials have been inconsistent, so the methods under study are not recommended by current practice guidelines.

A disease management approach to HF has been shown to reduce hospitalizations and increase the percentage of patients receiving ideal, guideline-recommended therapy. Recent studies demonstrate that disease management programs need not be confined to the outpatient setting and that hospital-based disease management systems can also improve medical care and education of patients hospitalized with HF and accelerate use of evidence-based, guideline-recommended therapies by administering them before hospital discharge.²⁹ Although disease management strategies can lead to improved survival, it is not clear that these strategies are necessarily more cost effective. Accordingly, the biggest challenge to disease management programs will be to determine how to support the additional personnel required in this model of care.

PATIENTS WITH REFRACTORY END-STAGE HEART FAILURE

Most patients with HFrEF respond well to evidence-based pharmacologic and nonpharmacologic treatments and enjoy a good quality of life with a meaningful prolongation of life. For reasons that are not clear, however, some patients do not improve or will experience a rapid recurrence of symptoms despite optimal medical and device therapies. These patients have the most advanced stage of HF (stage D) and should be considered for specialized treatment strategies, such as mechanical circulatory support (see Chapter 29), continuous intravenous positive inotropic therapy, or referral for cardiac transplantation (see Chapter 28). Before a diagnosis of refractory HF is made, careful evaluation to identify any contributing conditions (see Table 25-6), and to ensure that all conventional medical

strategies have been optimally used (see Fig. 25-18), is indicated. When no further therapies are appropriate, careful discussion of the prognosis and options for end-of life care should be initiated (see Chapter 31).

FUTURE PERSPECTIVES

As reviewed in this chapter, treatment with ACE inhibitors/ARBs, aldosterone antagonists, and beta blocker therapy and cardiac devices has substantially improved quality and quantity of life for patients with HFrEF. Unfortunately, we appear to be reaching a “ceiling” with regard to further antagonism of neurohormonal systems, inasmuch as most recent trials attempting to add additional neurohormonal inhibition to background therapy of ACE inhibition, beta blockade, and aldosterone antagonism have been unsuccessful (e.g., using aliskiren). This recent experience indicates the potential limits of neurohormonal inhibitory strategies and strongly signals that different drug development approaches are now needed. Currently, these approaches are under way, with new small molecules, cell replacement therapy (see Chapter 30), and gene therapy (see Chapter 30), accompanied by growing appreciation of the role of pharmacogenetics (see Chapter 9). Further refinement of device technology and appropriate patient selection may allow device therapies, especially CRT, to be extended to a larger number of eligible patients. It is likely that one or more of these therapies that target maladaptive mechanisms and/or cardiac remodeling will be successful in the near term.

GUIDELINES

Management of Heart Failure with a Reduced Ejection Fraction

Douglas L. Mann

A joint task force of the American College of Cardiology and the American Heart Association (ACC/AHA) published updated guidelines for the evaluation and management of HF in 2013.¹ These guidelines replaced previous sets of recommendations issued by the ACC/AHA in 2005² and updated in 2009.³ New guidelines from the Heart Failure Society were published in 2010,⁴ which superseded guidelines published in 2006.⁴ The European Society (ESC) guidelines for the diagnosis and treatment of chronic HF were published in 2012,⁵ which superseded guidelines in 2008.⁶

As reviewed in this chapter, the ACC/AHA guidelines classify patients into groups defined by four stages: stage A—patients at high risk for developing HF but without structural disorders of the heart; stage B—patients with a structural disorder of the heart but no symptoms of HF; stage C—patients with past or current symptoms of HF associated with underlying structural heart disease; and stage D—patients with end-stage disease who require specialized treatment strategies such as mechanical circulatory support, continuous inotropic infusions, cardiac transplantation, or hospice care. The guidelines are organized into recommendations for each stage (Fig. 25G-1). As with other ACC/AHA guidelines, these recommendations

classify interventions into one of three classes as follows, including two levels of the intermediate group:

Class I: Procedure/treatment *should* be performed/administered (benefit >>> risk).

Class IIa: Additional studies with focused objectives needed. *It is reasonable* to perform procedure/administer treatment (benefit >>> risk).

Class IIb: Additional studies with broad objectives needed; additional registry data would be helpful. Procedure/treatment *may* be considered (benefit ≥ risk).

Class III: No benefit (not helpful and of no proven benefit) OR Class III: Harm (excessive cost without benefit or harmful).

The ACC/AHA guidelines also adopt a convention for rating levels of evidence on which recommendations have been based: Level A recommendations are derived from data for multiple populations with data from multiple randomized clinical trials and/or meta-analyses; level B recommendations are derived from data from limited populations with data from a single randomized clinical trial or nonrandomized studies; and level C recommendations are based on very limited populations or the consensus opinion of experts or case studies or standard of care. The guidelines emphasize that the strength of evidence does not necessarily reflect the strength of a recommendation. A treatment may be controversial despite having been evaluated in controlled clinical trials; conversely, a strong recommendation may be supported only by historical data or by no data at all. New for the current set of guidelines is the introduction of the term *guideline-directed medical therapy* (GDMT), which represents optimal medical therapy as defined by the ACC/AHA guideline-recommended therapies (primarily class I).

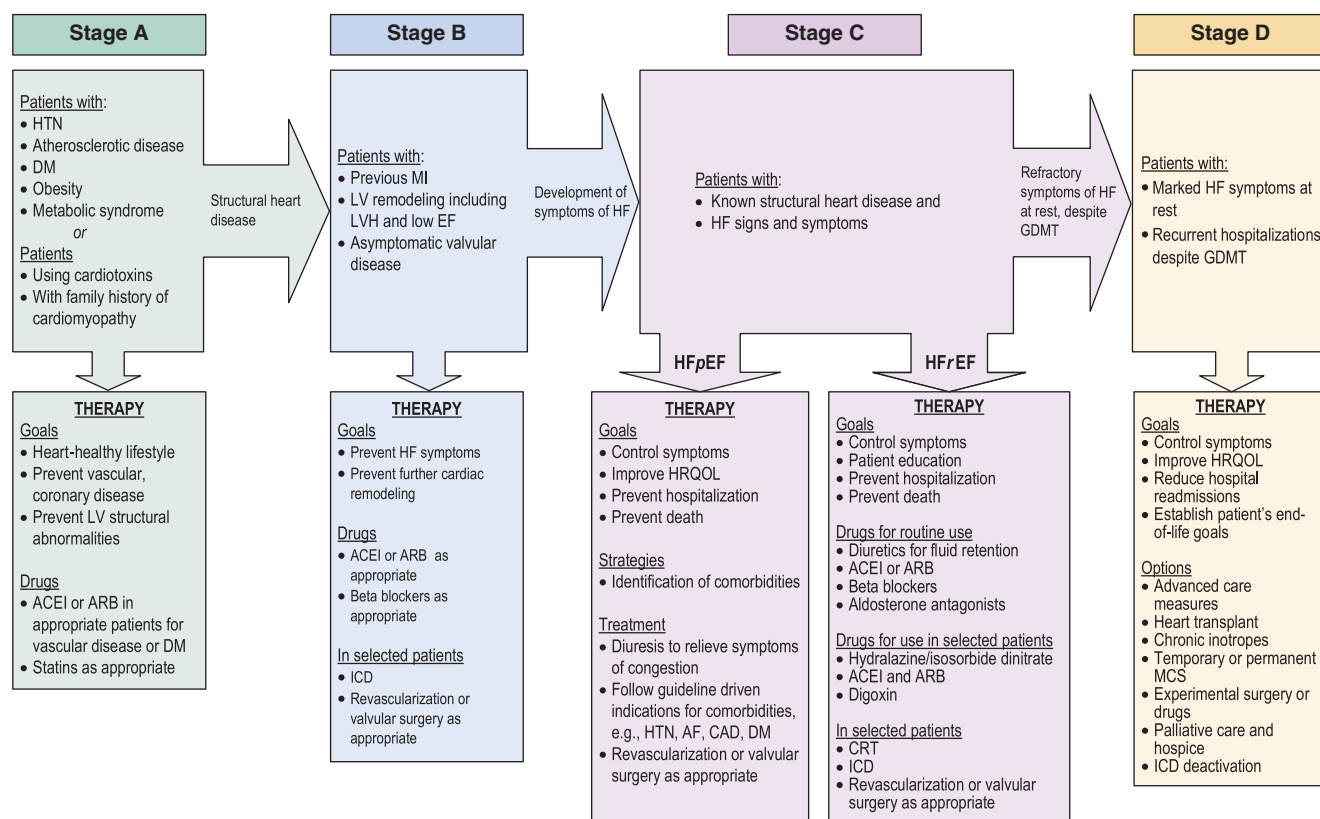

FIGURE 25G-1 Stages in the development of HF and recommended therapy by stage. ACEI = ACE inhibitor; AF = atrial fibrillation; DM = diabetes mellitus; HRQOL = health-related quality of life; HTN = hypertension; LVH = LV hypertrophy; MCS = mechanical circulatory support. (Modified from Hunt SA, Abraham WT, Chin MH, et al: 2009 focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the International Society for Heart and Lung Transplantation. *Circulation* 119:e391, 2009; and Yancy CW, Jessup M, Bozkurt B, et al: 2013 ACCF/AHA guideline for the management of heart failure: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 127:e147, 2013.)

INITIAL PATIENT EVALUATION

The ACC/AHA guidelines state that a complete history and physical examination should be the first step in the evaluation of patients with HF (Table 25G-1). This evaluation may provide insight into the cause of the HF and document the presence or absence of structural cardiovascular abnormalities. Other issues to be addressed include presence

or absence of history of diabetes, rheumatic fever, chest irradiation, exposure to cardiotoxic drugs, and use or abuse of alcohol, illicit drugs, or alternative therapies. The patient's functional and volume status also should be evaluated to assess prognosis and guide management. New recommendations include a three-generation family history for patients with dilated cardiomyopathy and the use of validated multivariable risk models for assessing subsequent mortality risk.

TABLE 25G-1 ACC/AHA Guidelines for Initial and Serial Evaluation of Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
History, Physical Examination, and Risk Scoring		
I	A thorough history and physical examination should be obtained/performed in patients presenting with HF to identify cardiac and noncardiac disorders or behaviors that might cause or accelerate the development or progression of HF. In patients with idiopathic DCM, a three-generational family history should be obtained to aid in establishing the diagnosis of familial DCM.	C
	Volume status and vital signs should be assessed at each patient encounter. This includes serial assessment of weight, as well as estimates of jugular venous pressure and the presence of peripheral edema or orthopnea.	B
Ila	Validated multivariable risk scores can be useful to estimate subsequent risk of mortality in ambulatory or hospitalized patients with HF.	C
Diagnostic Tests and Biomarkers		
I	Initial laboratory evaluation of patients presenting with HF should include complete blood count, urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen, serum creatinine, glucose, fasting lipid profile, liver function tests, and thyroid-stimulating hormone.	C
	Serial monitoring, when indicated, should include serum electrolytes and renal function.	C
	A 12-lead ECG should be performed initially on all patients presenting with HF.	C
	In ambulatory patients with dyspnea, measurement of BNP or N-terminal pro-B-type natriuretic (NT-proBNP) is useful to support clinical decision making regarding the diagnosis of HF, especially in the setting of clinical uncertainty, and measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF.	A
Ila	Screening for hemochromatosis or HIV is reasonable in selected patients who present with HF.	C
	Diagnostic tests for rheumatologic diseases, amyloidosis, or pheochromocytoma are reasonable in patients presenting with HF in whom there is a clinical suspicion of these diseases.	C
	BNP- or NT-proBNP-guided HF therapy can be useful to achieve optimal dosing of GDMT in select clinically euvolemic patients followed in a well-structured HF disease management program.	B
Ilb	The usefulness of serial measurement of BNP or NT-proBNP to reduce hospitalization or mortality in patients with HF is not well established. The measurement of other clinically available tests such as biomarkers of myocardial injury or fibrosis may be considered for additive risk stratification in patients with chronic HF.	B
Noninvasive Cardiac Imaging		
I	Patients with suspected or new-onset HF, or those presenting with acute decompensated HF, should undergo a chest x-ray to assess heart size and pulmonary congestion and to detect alternative cardiac, pulmonary, and other diseases that may cause or contribute to the patient's symptoms.	C
	A 2-dimensional echocardiogram with Doppler should be performed during initial evaluation of patients presenting with HF to assess ventricular function, size, wall thickness, wall motion, and valve function.	C
	Repeat measurement of EF and measurement of the severity of structural remodeling are useful to provide information in patients with HF who have had a significant change in clinical status; who have experienced or recovered from a clinical event; who have received treatment, including GDMT, that might have had a significant effect on cardiac function; or who may be candidates for device therapy.	C
Ila	Noninvasive imaging to detect myocardial ischemia and viability is reasonable in patients presenting with de novo HF who have known CAD and no angina unless the patient is not eligible for revascularization of any kind.	C
	Viability assessment is reasonable in select situations when planning revascularization in patients with HF and CAD	B
	Radionuclide ventriculography or magnetic resonance imaging can be useful to assess LVEF and volume when echocardiography is inadequate	C
	Magnetic resonance imaging is reasonable when assessing myocardial infiltrative processes or scar burden	B
III: No benefit	Routine repeat measurement of LV function assessment in the absence of clinical status change or treatment interventions should not be performed.	B
Invasive Evaluation		
I	Invasive hemodynamic monitoring with a pulmonary artery catheter should be performed to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment.	C
Ila	Invasive hemodynamic monitoring can be useful for carefully selected patients with acute HF who have persistent symptoms despite empirical adjustment of standard therapies and (1) whose fluid status, perfusion, or systemic or pulmonary vascular resistance is uncertain; (2) whose systolic pressure remains low, or is associated with symptoms, despite initial therapy; (3) whose renal function is worsening with therapy; (4) who require parenteral vasoactive agents; or (5) who may need consideration for mechanical circulatory support or transplantation.	C
	When ischemia may be contributing to HF, coronary arteriography is a reasonable test for patients eligible for revascularization.	C
	Endomyocardial biopsy can be useful in patients presenting with HF when a specific diagnosis is suspected that would influence therapy.	C
III (no benefit)	Routine use of invasive hemodynamic monitoring is not recommended in normotensive patients with acute decompensated HF and congestion with symptomatic response to diuretics and vasodilators.	B
III (harm)	Endomyocardial biopsy should not be performed in the routine evaluation of patients with HF.	C

BNP = B-type natriuretic peptide; DCM = dilated cardiomyopathy.

The guidelines recommend that the initial evaluation should include a complete blood count, urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen, serum creatinine, glucose, fasting lipid profile, liver function tests, and thyroid-stimulating hormone and that serial monitoring of electrolytes should be performed when indicated. The guidelines also recommend a chest radiograph and a 12-lead electrocardiogram; two-dimensional echocardiography with Doppler studies to assess LV function and detect underlying myocardial, valvular, or pericardial disease was considered a more valuable initial test than radionuclide ventriculography or magnetic resonance imaging. Screening for hemochromatosis, amyloidosis, human immunodeficiency virus infection, sleep-disordered breathing, connective tissue diseases, amyloidosis, or pheochromocytoma also may be a reasonable step in selected patients.

Both the updated ACC/AHA and the European Society of Cardiology guidelines reflect recent research on biomarkers, including BNP and NT-proBNP. The 2013 ACC/AHA guidelines give a class I (level of evidence, A) recommendation for the measurement of BNP or NT-proBNP in ambulatory patients with dyspnea to support clinical decision making regarding the diagnosis of HF, especially in the setting of clinical uncertainty, and measurement of these two biomarkers is useful for establishing prognosis or disease severity in chronic HF.

Screening for and assessment of CAD in patients with HF are given less weight in the 2013 ACC/AHA guidelines than in previous guidelines. When ischemia may be contributing to HF, the guidelines indicate that coronary arteriography is reasonable for patients eligible for revascularization (class IIa; level of evidence, C). The guidelines also support noninvasive imaging to detect myocardial ischemia and viability in patients presenting with de novo HF who have known CAD and no angina, unless the patient is not eligible for revascularization of any kind, as well as viability testing in select patients in planning revascularization (class IIa; level of evidence, B-C). Although the guidelines support the use of endomyocardial biopsy in patients presenting with HF when a diagnosis that would influence therapy is suspected (class IIb; level of evidence, C), the routine use of this procedure biopsy is not recommended (class III: harm). The

guidelines do not support serial measurement of LV function in the absence of change in clinical status. The updated ACC/AHA guidelines now give a class I (level of evidence, C) recommendation the use of invasive hemodynamic monitoring with a pulmonary artery catheter to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment (see Chapter 24 for guidelines for management of hospitalized patients with HF).

TREATMENT OF PATIENTS AT HIGH RISK FOR DEVELOPING HEART FAILURE (STAGE A)

The 2013 ACC/AHA guidelines for management of patients in stage A (Table 25G-2) are simplified from previous guidelines and continue to provide strong recommendations (class I) for treating hypertension and lipid disorders in accordance with contemporary guidelines to lower the risk of HF. The guidelines also suggest that other conditions or factors that may lead to or contribute to HF, such as obesity, diabetes mellitus, tobacco use, and exposure to known cardiotoxic agents, should be controlled or avoided.

TREATMENT OF PATIENTS WITH LEFT VENTRICULAR DYSFUNCTION WHO HAVE NOT DEVELOPED SYMPTOMS (STAGE B)

The goal of therapy in stage B HF is to reduce the risk of further damage to the heart and to minimize the rate of progression of LV dysfunction (Table 25G-3). In the absence of contraindications, beta blockers and ACE inhibitors (or ARBs in those intolerant of ACE inhibitors) are recommended for all patients with a history of MI, regardless of EF and for all patients with diminished EF, regardless of history of MI (class I; level of evidence, A-C). By contrast, the guidelines discourage use of calcium channel blockers with negative

TABLE 25G-2 ACC/AHA Guidelines for Treating Patients at High Risk for Development of Heart Failure (Stage A)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Hypertension and lipid disorders should be controlled in accordance with contemporary guidelines to lower the risk of HF.	A
	Other conditions that may lead to or contribute to HF, such as obesity, diabetes mellitus, tobacco use, and known cardiotoxic agents, should be controlled or avoided.	C

TABLE 25G-3 ACC/AHA Guidelines for Treatment of Asymptomatic Left Ventricular Systolic Dysfunction (Stage B)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	In all patients with a recent or remote history of MI or ACS and reduced EF, ACE inhibitors should be used to prevent symptomatic HF and reduce mortality. In patients intolerant of ACE inhibitors, ARBs are appropriate unless contraindicated.	A
	In all patients with a recent or remote history of MI or ACS and reduced EF, evidence-based beta blockers should be used to reduce mortality.	B
	Beta blockade and ACE inhibition should be used in all patients with a recent or remote history of MI regardless of ejection fraction or presence of HF.	
	In all patients with a recent or remote history of MI or ACS, statins should be used to prevent symptomatic HF and cardiovascular events.	A
	Blood pressure should be controlled in accordance with clinical practice guidelines for hypertension to prevent symptomatic HF.	A
	ACE inhibitors should be used in all patients with a reduced EF to prevent symptomatic HF.	A
	Beta blockers should be used in all patients with a reduced EF to prevent symptomatic HF.	C
IIa	To prevent sudden death, placement of an ICD is reasonable in patients with asymptomatic ischemic cardiomyopathy who are at least 40 days post-MI, have an LVEF of 30% or less, are on appropriate medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year.	B
III: Harm	Nondihydropyridine calcium channel blockers with negative inotropic effects may be harmful in asymptomatic patients with low LVEF and no symptoms of HF after MI.	B

inotropic action in this population. The guidelines also support the use of an ICD (class IIb; level of evidence, B) in patients with asymptomatic ischemic cardiomyopathy who have had a recent (within 40 days) MI, with EF of 30% or less, and who are on appropriate medical therapy and have a reasonable expectation of life for longer than 1 year (for a review of ICD guidelines, see “Cardiac Resynchronization and Implantable Cardioverter Defibrillators in Heart Failure with a Reduced Ejection Fraction” at the end of [Chapter 26](#)).

TREATMENT OF PATIENTS WITH LEFT VENTRICULAR DYSFUNCTION AND CURRENT OR PREVIOUS SYMPTOMS (STAGE C)

Application of the same measures recommended for preventing or minimizing progression of LV dysfunction for patients in stage A and B is supported for patients in stage C, who have current or previous symptoms attributable to LV dysfunction ([Table 25G-4](#)). Physical

activity and cardiac rehabilitation are recommended for stage C patients. The updated guidelines also reflect the results of the recent HF-ACTION trial (discussed in this chapter), in which exercise training did not have a favorable impact on all-cause mortality or HF-related hospitalization. Maximal exercise testing with or without measurement of respiratory gas exchange to facilitate an appropriate exercise program, which was a class IIa indication in 2009, is not recommended in the 2013 ACC/AHA guidelines, although it is still recommended in the 2012 ESC guidelines.

The 2013 ACC/AHA updated guidelines support the use of beta blockers (bisoprolol, carvedilol, and sustained-release metoprolol succinate) and ACE inhibitors (or ARBs in patients who cannot tolerate ACE inhibitors) for all stage C HF patients, in the absence of contraindications, and the use of diuretics for patients with fluid overload. Based on the results of the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF), discussed in this chapter, aldosterone antagonists are now recommended for all patients with NYHA class II to IV HF with an EF of 35% or less, to

TABLE 25G-4 ACC/AHA Guidelines for Treatment of Symptomatic Left Ventricular Systolic Dysfunction (Stage C)

CLASS	INDICATION	LEVEL OF EVIDENCE
Nonpharmacologic Interventions		
I	Patients with HF should receive specific education to facilitate HF self-care.	B
	Exercise training (or regular physical activity) is recommended as safe and effective for patients with HF who are able to participate to improve functional status.	A
IIa	Cardiac rehabilitation can be useful in clinically stable patients with HF to improve functional capacity, exercise duration, HRQOL, and mortality.	B
	Sodium restriction is reasonable for patients with symptomatic HF to reduce congestive symptoms.	C
	Continuous positive airway pressure (CPAP) can be beneficial to increase LVEF and improve functional status in patients with HF and sleep apnea.	B
Pharmacologic Interventions		
I	Measures listed as class I recommendations for patients in stages A and B are recommended where appropriate. GDMT should be the mainstay of pharmacologic therapy for HFrEF.	A, B, C A
Diuretics		
I	Diuretics are recommended in patients with HFrEF who have evidence of fluid retention, unless contraindicated, to ameliorate symptoms.	C
Angiotensin-Converting Enzyme Inhibitors/Adrenergic Receptor Blockers		
I	ACE inhibitors are recommended in patients with HFrEF and current or previous symptoms, unless contraindicated, to reduce morbidity and mortality.	A
	ARBs are recommended in patients with HFrEF with current or previous symptoms who are ACE inhibitor-intolerant, unless contraindicated, to reduce morbidity and mortality.	A
IIa	ARBs are a reasonable choice to reduce morbidity and mortality as alternatives to ACE inhibitors for first-line therapy in patients with HFrEF, especially in those already taking ARBs for other indications, unless contraindicated.	A
IIb	Addition of an ARB may be considered in persistently symptomatic patients with HFrEF who are already being treated with an ACE inhibitor and a beta blocker in whom an aldosterone antagonist is not indicated or tolerated.	A
III: Harm	Routinely combining an ACE inhibitor, an ARB, and an aldosterone antagonist.	C
Beta Blockers		
I	Use of one of the three beta blockers proven to reduce mortality (i.e., bisoprolol, carvedilol, and sustained-release metoprolol succinate) is recommended for all patients with current or previous symptoms of HFrEF, unless contraindicated, to reduce morbidity and mortality.	A
Aldosterone Receptor Antagonists		
I	Aldosterone receptor antagonists (or mineralocorticoid receptor antagonists) are recommended in patients with NYHA class II-IV and LVEF of 35% or less, unless contraindicated, to reduce morbidity and mortality.	A
I	Aldosterone receptor antagonists are recommended to reduce morbidity and mortality after an acute MI in patients with LVEF of 40% or less who develop symptoms of HF or who have a history of diabetes mellitus, unless contraindicated.	B
III: Harm	Inappropriate use of aldosterone receptor antagonists is potentially harmful because of life-threatening hyperkalemia or renal insufficiency when serum creatinine is >2.5 mg/dL in men or >2.0 mg/dL in women (or estimated glomerular filtration rate < 30 mL/min/1.73 m ²), and/or potassium > 5.0 mEq/Liter.	B
Hydralazine and Isosorbide Dinitrate		
I	The combination of hydralazine and isosorbide dinitrate is recommended to reduce morbidity and mortality for patients self-described as African Americans with NYHA class III-IV HFrEF receiving optimal therapy with ACE inhibitors and beta blockers, unless contraindicated.	A
IIa	A combination of hydralazine and isosorbide dinitrate can be useful to reduce morbidity or mortality in patients with current or previous symptomatic HFrEF who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated.	B
Digoxin		
IIa	Digoxin can be beneficial in patients with HFrEF, unless contraindicated, to decrease hospitalizations for HF.	B

Continued

TABLE 25G-4 ACC/AHA Guidelines for Treatment of Symptomatic Left Ventricular Systolic Dysfunction (Stage C)—cont'd

CLASS	INDICATION	LEVEL OF EVIDENCE
	Anticoagulation	
I	Patients with chronic HF with permanent/persistent/paroxysmal atrial fibrillation and an additional risk factor for cardioembolic stroke (history of hypertension, diabetes mellitus, previous stroke or transient ischemic attack, or ≥ 75 years of age) should receive chronic anticoagulant therapy.	A
I	The selection of an anticoagulant agent (warfarin, dabigatran, apixaban, or rivaroxaban) for permanent/persistent/paroxysmal atrial fibrillation should be individualized on the basis of risk factors, cost, tolerability, patient preference, potential for drug interactions, and other clinical characteristics, including time in the international normalized ratio therapeutic range if the patient has been taking warfarin.	C
IIa	Chronic anticoagulation is reasonable for patients with chronic HF who have permanent/persistent/paroxysmal atrial fibrillation but no additional risk factor for cardioembolic stroke.	B
III: No benefit	Anticoagulation is not recommended in patients with chronic HFrEF without atrial fibrillation, a previous thromboembolic event, or a cardioembolic source.	B
	Statins	
III: No benefit	Statins are not beneficial as adjunctive therapy when prescribed solely for HF.	A
	Omega-3 Fatty Acids	
IIa	Omega-3 PUFA supplementation is reasonable to use as adjunctive therapy in patients with NYHA class II-IV symptoms and HFrEF or HFpEF, unless contraindicated, to reduce mortality and cardiovascular hospitalizations.	B
	Drugs of Unproven Value or That May Cause harm	
III: No benefit	Nutritional supplements as treatment for HF are not recommended in patients with current or previous symptoms of HFrEF.	B
	Hormonal therapies other than to correct deficiencies are not recommended for patients with current or previous symptoms of HFrEF.	C
III: Harm	Drugs known to adversely affect the clinical status of patients with current or previous symptoms of HFrEF are potentially harmful and should be avoided or withdrawn whenever possible (e.g., most antiarrhythmic drugs, most calcium channel-blocking drugs [except amlodipine], NSAIDs, or thiazolidinediones).	B
	Long-term use of infused positive inotropic drugs is potentially harmful for patients with HFrEF, except as palliation for patients with end-stage disease who cannot be stabilized with standard medical treatment (see recommendations for stage D).	C
	Calcium Channel Blockers	
III: No benefit	Calcium channel blocking drugs are not recommended for routine therapy in patients with HFrEF.	A

HRQOL = health-related quality of life.

reduce morbidity and mortality, unless contraindicated (class I; level of evidence, A). As with the 2009 guidelines, the use of hydralazine and isosorbide remains a class I indication for self-identified African Americans who remain symptomatic in NYHA class III to IV HF despite optimal therapy. The combination of hydralazine and isosorbide is recommended in patients who are intolerant of an ACE inhibitor or an ARB. Digitalis remains a reasonable approach to decrease hospitalizations in symptomatic patients. Based on the results of the WARCEF (Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction study, discussed in this chapter), anticoagulation is not recommended in patients with chronic HF without atrial fibrillation, a previous embolic event, or a recognized cardioembolic source (class III: no benefit). However, anticoagulation continues to be recommended for patients with chronic HF and permanent/persistent/paroxysmal atrial fibrillation who have an additional risk factor for cardioembolic stroke (class I; level of evidence, B). The guidelines explicitly discourage the routine use of a combination of an ACE inhibitor, ARB, and aldosterone antagonist; calcium channel blockers, long-term infusion of positive inotropic drugs (except as palliation in patients with end-stage disease; see [Table 25G-5](#)), use of nutritional supplements, statins as adjunctive therapy for HF, and hormonal therapies other than those needed to replete deficiencies. The recommendations regarding the use of ICDs and CRT are reviewed in [Chapter 26](#) and the ICD guidelines section at the end of that chapter.

TREATMENT OF PATIENTS WITH REFRACTORY END-STAGE HEART FAILURE (STAGE D)

The 2009 ACCF/AHA HF guidelines define stage D as patients with truly refractory HF who might be eligible for specialized, advanced

treatment strategies, such as mechanical circulatory support (MCS [[see Chapter 29](#)]), procedures to facilitate fluid removal, continuous inotropic infusions, or cardiac transplantation ([see Chapter 28](#)) or other innovative or experimental surgical procedures, or for end-of-life care, such as hospice ([see Chapter 31](#)). The guidelines provide clear indications for the use of inotropic agents and MCS in patients in stage D ([Table 25G-5](#)). The guidelines endorse the use of continuous intravenous inotropic support until definitive therapy can be performed (e.g., MCS, heart transplantation), and/or to maintain systemic perfusion and preserve end-organ performance until the acute precipitating problem is resolved (class I; level of evidence, C). The guidelines also support inotropic support as “bridge therapy” to GDMT and/or device therapy (class IIa; level of evidence, B), as well as short-term continuous intravenous inotropic agents in hospitalized patients with documented severe systolic dysfunction who present with low blood pressure and significantly depressed cardiac output, to maintain systemic perfusion and preserve end-organ performance, or as palliative therapy for symptom control (class IIb; level of evidence, B). The guidelines regard long-term use of either continuous or intermittent, intravenous positive inotropic agents, in the absence of specific indications or for reasons other than palliative care, as potentially harmful (class III: harm; level of evidence, B).

The 2013 ACC/AHA provide qualified support for MCS in carefully selected patients with stage D HFrEF, in whom definitive management (e.g., cardiac transplantation) or cardiac recovery is anticipated or planned, and also indicate that percutaneous and extracorporeal ventricular assist devices (VADs) are a reasonable option as a “bridge to recovery” or “bridge to decision” for carefully selected patients with HFrEF with acute profound hemodynamic compromise (class IIb; level of evidence, B). The guidelines also provide qualified support for the use of durable VADs to prolong survival in carefully

TABLE 25G-5 ACC/AHA Guidelines for Treatment of Patients with End-Stage Heart Failure (Stage D)

CLASS	INDICATION	LEVEL OF EVIDENCE
Nonpharmacologic Interventions		
Ila	Fluid restriction (1.5 to 2 L/day) is reasonable in stage D, especially in patients with hyponatremia.	B
Inotropic Support		
I	Until definitive therapy (e.g., coronary revascularization, MCS, heart transplantation) or resolution of the acute precipitating problem, patients with cardiogenic shock should receive temporary intravenous inotropic support to maintain systemic perfusion and preserve end-organ performance.	C
Ila	Continuous intravenous inotropic support is reasonable as “bridge therapy” in patients with stage D refractory to GDMT and device therapy who are eligible for and awaiting MCS or cardiac transplantation.	B
Ilb	Short-term, continuous intravenous inotropic support may be reasonable in those hospitalized patients presenting with documented severe systolic dysfunction who present with low blood pressure and significantly depressed cardiac output to maintain systemic perfusion and preserve end-organ performance.	B
	Long-term, continuous intravenous inotropic support may be considered as palliative therapy for symptom control in select patients with stage D disease despite optimal GDMT and device therapy who are not eligible for either MCS or cardiac transplantation.	B
III: Harm	Long-term use of either continuous or intermittent, intravenous parenteral positive inotropic agents, in the absence of specific indications or for reasons other than palliative care, is potentially harmful in the patient with HF.	B
	Use of parenteral inotropic agents in hospitalized patients without documented severe systolic dysfunction, low blood pressure, or impaired perfusion, and evidence of significantly depressed cardiac output, with or without congestion, is potentially harmful.	B
Mechanical Circulatory Support (MCS)		
Ila	MCS is beneficial in carefully selected patients with stage D HFrEF in whom definitive management (e.g., cardiac transplantation) or cardiac recovery is anticipated or planned).	B
	Nondurable MCS, including the use of percutaneous and extracorporeal ventricular assist devices (VADs), is reasonable as a “bridge to recovery” or “bridge to decision” for carefully selected patients with HFrEF with acute, profound hemodynamic compromise.	B
	Durable MCS is reasonable to prolong survival for carefully selected patients with stage D HFrEF.	B
Cardiac Transplantation		
I	Evaluation for cardiac transplantation is indicated for carefully selected patients with stage D HF despite GDMT, device, and surgical management.	C

selected patients with stage D HFrEF. As in previous guidelines cardiac transplantation remains a class I indication (level of evidence, C) for carefully selected patients with stage D HFrEF despite GDMT and device and surgical management.

COMORBID CONDITIONS IN PATIENTS WITH HEART FAILURE

The 2013 ACC/AHA practice guidelines recognize the importance of comorbid conditions in the management of HF, including hypertension, anemia, diabetes, arthritis, chronic kidney disease, and depression. However, the guidelines did not generate specific recommendations, reflecting the status of current evidence.

THE HOSPITALIZED PATIENT

The updated 2010 Heart Failure Society of America (HFSA), 2012 ESC and 2013 ACC/AHA guidelines included specific recommendations regarding the hospitalized patient and are summarized in Table 24G-1 (Chapter 24 Guidelines section).

HEART FAILURE WITH A PRESERVED EJECTION FRACTION

The updated 2010 HFSA, 2012 ESC and 2013 ACC/AHA guidelines included specific recommendations regarding management of patients with HFpEF and are summarized in Table 27G-1 (Chapter 27 Guidelines section).

SURGICAL/PERCUTANEOUS/TRANSCATHETER INTERVENTIONAL TREATMENTS OF HEART FAILURE

The 2013 ACC/AHA guidelines reviewed surgical therapies and percutaneous interventions that are commonly integrated in the management of patients with HF, including coronary revascularization (e.g., CABG, angioplasty, stenting); aortic valve replacement, mitral valve replacement and LV surgical reconstruction (Table 25G-6). The revised guidelines recommend coronary artery revascularization via CABG or percutaneous intervention for patients on GDMT with angina and suitable coronary artery anatomy, especially for a left main artery stenosis (>50%) or left main equivalent disease (class I; level of evidence, C). CABG also was recommended to improve survival in mild to moderate LV dysfunction (EF 35% to 50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal left anterior descending coronary artery stenosis when viable myocardium is present, as well as to decrease morbidity and cardiovascular mortality for patients with severe LV dysfunction (EF < 35%), HF, and significant CAD (class IIa; level of evidence, B). Qualified support was provided for a survival benefit for CABG (class IIb; level of evidence, B) in patients with ischemic heart disease with severe LV systolic dysfunction (EF < 35%) and operable coronary artery anatomy irrespective of whether viable myocardium was present. The new guidelines provided a class IIa (level of evidence, B) recommendation for surgical aortic valve replacement in patients with a predicted surgical mortality of less than 10% and a class IIa (level of evidence, B) recommendation for transcatheter aortic valve replacement in inoperable patients with critical aortic valve disease. The guidelines offer qualified support for transcatheter mitral valve repair or mitral valve surgery for functional mitral insufficiency and recommend this approach should be considered after careful candidate selection and in addition to GDMT (class IIb; level of evidence, B). A similar level

TABLE 25G-6 ACC/AHA Guidelines for Surgical/Percutaneous/Transcatheter Interventional Treatments of Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Coronary artery revascularization via CABG or percutaneous intervention is indicated for patients (HFpEF and HFrEF) on GDMT with angina and suitable coronary artery anatomy, especially for a left main artery stenosis (>50%) or left main–equivalent disease.	C
IIa	CABG to improve survival is reasonable in patients with mild to moderate LV systolic dysfunction (EF 35%-50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal left anterior descending coronary artery stenosis when viable myocardium is present in the region of intended revascularization.	B
	CABG or medical therapy is reasonable to improve morbidity and cardiovascular mortality for patients with severe LV dysfunction (EF <35%), HF, and significant CAD.	B
	Surgical aortic valve replacement is reasonable for patients with critical aortic stenosis and a predicted surgical mortality of no greater than 10%.	B
	Transcatheter aortic valve replacement after careful candidate consideration is reasonable for patients with critical aortic stenosis who are deemed inoperable.	B
IIb	CABG may be considered with the intent of improving survival in patients with ischemic heart disease with severe LV systolic dysfunction (EF <35%) and operable coronary anatomy whether or not viable myocardium is present.	B
	Transcatheter mitral valve repair or mitral valve surgery for functional mitral insufficiency is of uncertain benefit and should only be considered after careful candidate selection and with a background of GDMT.	B
	Surgical reverse remodeling or LV aneurysmectomy may be considered in carefully selected patients with HFrEF for specific indications, including intractable HF and ventricular arrhythmias.	B

TABLE 25G-7 Coordinating Care for Patients With Chronic Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Effective systems of care coordination with special attention to care transitions should be deployed for every patient with chronic HF that facilitate and ensure effective care that is designed to achieve GDMT and prevent hospitalization.	B
	Every patient with HF should have a clear, detailed, and evidence-based plan of care that ensures the achievement of GDMT goals, effective management of comorbid conditions, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with secondary prevention guidelines for cardiovascular disease. This plan of care should be updated regularly and made readily available to all members of the patient's health care team.	C
	Palliative and supportive care is effective for patients with symptomatic advanced HF to improve quality of life.	B

of qualified support was given for surgical reverse remodeling or LV aneurysmectomy for intractable HF and ventricular arrhythmias

COORDINATING CARE FOR PATIENTS WITH CHRONIC HEART FAILURE

The guidelines recognize that systems of care designed to support patients with HF and other cardiac diseases can produce significant improvement in outcomes, but indicate that the quality of evidence is mixed for specific components of HF clinical management interventions, such as home-based care, disease management and remote telemonitoring programs. Hence, the guidelines recommend that interventions should focus on improving adherence to GDMT (**Table 25G-7**). The updated guidelines advocate patient education, and involvement of patients with HF and their families, especially during transitions of care, to ensure effective care that is designed to achieve GDMT and prevent hospitalizations (class I; level of evidence, B). The guidelines also recommend that every patient with HF should have a clear, detailed, and evidence-based plan of care that ensures the achievement of GDMT goals, effective management of comorbid conditions, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with Secondary Prevention Guidelines for cardiovascular disease (class I; level of evidence, C). The guidelines recommend that the HF and palliative care teams are best suited to help patients and families decide when

end-of-life care (including hospice) is appropriate (class I; level of evidence, C). The core elements of comprehensive palliative care for HF include expert symptom assessment and management, including symptom control, psychosocial distress, health related quality of life, preferences about end-of-life care, caregiver support, and assurance of access to evidence-based disease-modifying interventions.

PHARMACOGENETICS

The field pharmacogenetics attempts to define common gene polymorphisms, or sets of polymorphisms, that underlie variability in drug action (see Chapter 9). All current HF practice guidelines (see the guidelines on management of HFrEF at the end of this chapter) recommend titrating ACE inhibitors, angiotensin receptor blockers, aldosterone antagonists, and beta blockers to doses that have been shown to be beneficial in clinical trials. Although this approach tends to work well for most patients, it has two major shortcomings. The most obvious of these is that basing drug dosing on the doses selected in clinical trials does not allow for dose optimization in patients who may metabolize and/or distribute drug differently. The second problem is that clinical trials generally are designed to yield “binary” results. That is, a drug under investigation is deemed either beneficial or not beneficial in that the patients in the treatment arm will either have or have not attained a prespecified endpoint (e.g., death or hospitalization). A beneficial effect in a positive clinical trial implies that all patients will receive the same degree of benefit from the drug that is given. A more likely outcome, however, is that a given therapy will have a markedly positive impact for some patients and a more modest effect in others and may be completely ineffective or perhaps even harmful in a smaller group of treated patients. Thus, even though a drug is deemed beneficial in a clinical trial, there is no

guarantee that an individual patient will benefit from the treatment. For example, beta blockers have been shown consistently to reduce the risk of death in patients with HF by approximately 35% (see Fig. 25-17); however, clinical trials also have shown that beta blockers will need to be discontinued in 8% to 25% of patients with HF as a consequence of significant adverse effects, including worsening HF.¹ Recent advances in the field of pharmacogenetics suggest that a careful analysis of underlying gene polymorphisms within a given patient may enable clinicians to develop personalized therapeutic regimens for patients with HF. In view of the central role of the renin-angiotensin-aldosterone and adrenergic systems in the pathophysiology (see Chapter 22) and treatment of HF, it is perhaps not surprising that polymorphisms in the genes that regulate these pathway appear to influence the therapeutic efficacy of ACE inhibitors and/or beta blockers. Table e25-1 provides an overview of the major genetic variations in these pathways and the proposed functional impact of these polymorphisms and summarizes how these genetic polymorphisms influence traditional pharmacotherapeutic approaches in HF.

One of the most widely studied genetic variants is the ACE insertion/deletion (I/D) polymorphism, which involves a 287–base pair insertion or deletion within intron 16 of the *ACE* gene. Although the clinical significance of this polymorphism remains controversial, the physiologic association with ACE enzymatic activity has been demonstrated consistently. Studies have shown that persons with the DD genotype have the highest ACE activity and angiotensin II levels,

TABLE e25-1 Effect of Gene Polymorphisms on Pharmacologic Treatment of Heart Failure

PATHWAY/GENE	POLYMORPHISM	FUNCTIONAL IMPACT	IMPACT ON PHARMACOLOGICAL THERAPY
Renin-Angiotensin-Aldosterone System			
ACE	287-bp insertion (I) or deletion (D) in intron 16	DD genotype has increased ACE activity and worse clinical outcomes in some (but not all studies)	Beta blockers and ACE inhibitors attenuate adverse outcomes of DD genotype but have no effect on II/ID genotypes; II/ID genotype predicts reverse LV remodeling in response to spironolactone
Angiotensinogen	Methionine (Met)–threonine (Thr) switch at aa 235	Increased angiotensinogen levels with HTN	Modest risk of hypertension in whites; effect on drug responsiveness in HF not known
Aldosterone synthase	C-to-T transition at position –344 (T/C)	–344C allele associated with higher aldosterone levels	TT genotype associated with greater impact of fixed combination of isosorbide dinitrate and hydralazine on the event free survival in A-HeFT study
Adrenergic Nervous System			
Beta ₁ -AR	Arginine (Arg)–glycine (Gly) switch at aa 389	Arg 389 polymorphism has increased adenylyl cyclase activity 3× more in response to agonist than for Gly389 variant	Arg 389 Arg genotype associated with greatest improvement in EF with beta blockers and improved mortality with bucindolol treatment in BEST
Beta ₁ -AR	Serine (Ser)–glycine (Gly) switch at aa 49	In vitro, the Gly49 variant shows decreased receptor expression compared with Ser49 variant after exposure to isoproterenol (at 24 hr)	Ser49Ser genotype requires higher doses of beta blocker to achieve a mortality benefit
Beta ₂ -AR	Threonine (Thr)–isoleucine (Ile) switch at aa 164	Ile164 beta ₂ -AR has decreased affinity for catecholamine binding, decreased basal and epinephrine-stimulated adenylyl cyclase activity, and impaired agonist-promoted sequestration; Ile164 transgenic mice display depressed resting and agonist-stimulated contractile function in vivo compared with Thr164 mice	Associated with decreased Vo ₂ max and worse HF outcomes; effect on drug responsiveness in HF not known
GRK5	Glutamine (Gln)–leucine (Leu) at amino aa 49	GRK5-Leu41 uncouples isoproterenol-stimulated responses > GRK5-Gln41 in transfected cells and transgenic mice, and protects against experimental catecholamine-induced cardiomyopathy	GRK5-Leu41 is associated with decreased mortality in African Americans with HF or cardiac ischemia.
Alpha _{2C} -AR	alpha _{2C} Del322-325	Decreased NE uptake	Increased likelihood of developing HF in patients with the beta ₁ -AR Arg389 polymorphism; effect on drug responsiveness in HF not known

heterozygotes (I/D) have intermediate levels, and people who are homozygous for the I allele (I/I) have the lowest levels of ACE activity. The relationship of ACE I/D to numerous conditions including atherosclerosis, MI, LV hypertrophy, hypertrophic cardiomyopathy, and HF also has been explored. Although the current weight of evidence does not permit definitive conclusions regarding the overall contribution of the ACE I/D polymorphism to the clinical outcome in these conditions, growing evidence indicates that the ACE I/D polymorphism may predict drug responsiveness to both beta blockers and ACE inhibitors in patients with HF. In a study of patients with chronic HF, the ACE DD polymorphism was significantly associated with death or the need for transplantation when compared with patients with II or ID genotype. Within the ACE DD group, patients treated with beta blockers had significantly improved transplant-free survival when compared to patients not receiving beta blocker therapy, whereas beta blocker treatment had no effect in clinical outcomes in the II or ID groups.² In a similar study, patients with the DD genotype had better clinical outcomes when receiving high-dose ACE inhibitor therapy when compared with low-dose ACE inhibitor therapy, whereas the ACE dose had no effect on clinical outcomes in patients with the either the II or ID genotype. In this study, the regimen of high-dose ACE inhibitors and beta blockers had the greatest impact on transplant-free survival in patients with the DD variant.² Taken together, these findings suggest a differential clinical response to standard HF therapy based on the ACE I/D polymorphism.

Although the impact of genetic heterogeneity on HF outcomes has been extensively studied in predominantly white cohorts, few studies have investigated the impact of genomic variation in blacks. In a genetic substudy of the African-Americans in Heart Failure (A-HeFT) trial (see earlier), a single-nucleotide polymorphism within the promoter region of the aldosterone synthase gene (C-to-T transition at position -344) was shown to predict responsiveness to the fixed combination of hydralazine-isosorbide dinitrate.³ In A-HeFT treatment with the fixed combination of hydralazine-isosorbide dinitrate was associated with a markedly improved clinical outcome (mortality, HF hospitalization, and change in quality of life at 6 months) in the TT homozygotes but had no significant impact among subjects with the -344C allele, suggesting that genetic variations in aldosterone production may play an important role in disease progression in blacks with HF. Polymorphisms that affect the function of beta- or alpha-adrenergic receptors also may influence the pharmacologic response in patients with HF (see Table e25-1). Patients with a common polymorphism of the beta₁-adrenergic receptor (AR) that results in either an arginine (Arg) or glycine (Gly) substitution at amino acid position 389 exhibit different clinical responses to beta blockers. In the Bucindolol Evaluation of Survival Trial (BEST), bucindolol treated patients who were homozygous for the Arg 389 polymorphism (Arg389Arg) had improved clinical outcomes when compared with “glycine carriers” (Arg389Gly and Gly389Gly) who were treated with bucindolol, suggesting that the therapeutic response to beta blockers differs by genotype.⁴ The Arg389Arg

genotype was also associated with significantly greater reductions in LV end-diastolic and end-systolic diameters after treatment with beta blockers when compared with identically treated Gly389 carriers.⁵ The alpha_{2c}-adrenergic receptor inhibits norepinephrine release at cardiac presynaptic nerve endings through a negative feedback mechanism. The deletion of four consecutive amino acids in (aa 322-325) in the alpha_{2c}-adrenergic receptor results in loss of normal synaptic autoinhibitory feedback mechanism, and hence enhanced presynaptic release of norepinephrine. There appears to be an increased risk of developing HF when the alpha_{2c}Del322-325 and the Arg389 beta₁-AR polymorphism are both present (i.e., a diplotype).⁶ Although the impact of the alpha_{2c}Del322-325 and Arg389 beta₁-AR synergism on beta blocker responsiveness is not known, it is likely that patients with this diplotype may have increased responsiveness to beta blockers, based on what has been reported thus far for the Arg389 polymorphism. Recently a nonsynonymous polymorphism in which leucine (Leu) is substituted for glutamine (Gln) at amino acid position 49 of G protein receptor kinase 5 (GRK5-Leu41), which desensitizes beta-AR signaling, was shown to uncouple beta-AR signaling more effectively than did the GRK5-Gln41 polymorphism. Human association studies showed a pharmacogenomic interaction between GRK5-Leu41 and beta blocker treatment, in which the presence of the GRK5-Leu41 polymorphism was associated with decreased mortality in African Americans (in whom this polymorphism is more prevalent) with HF or cardiac ischemia. Subsequent studies showed that among patients not taking beta blockers, GRK5-Leu41 was associated with improved survival in African Americans suggesting that GRK5-Leu41 provides a “genetic beta blockade” that improves survival in African Americans with HF.⁷ In addition to contributing to the functional response to beta blockers, genetic polymorphisms that affect drug metabolism also may influence the therapeutic response to beta blockers. For example, genetic variants in the cytochrome P-450 (CYP) 2D6 gene have a marked effect on plasma concentrations of metoprolol and carvedilol. In subjects with a nonfunctional CYP2D6 enzyme (poor metabolizers), the peak plasma concentration of metoprolol is six times higher than in subjects with a normally functioning enzyme.¹

CARDIAC GLYCOSIDES

Cardiac glycosides are used to treat chronic HF in patients in sinus rhythm and to control the response of the ventricular rate to supraventricular arrhythmias, including atrial fibrillation.¹ Digoxin is the most commonly prescribed cardiac glycoside because of its convenient pharmacokinetics, alternative routes of administration, and the widespread availability of serum drug level measurements.

Mechanisms of Action

Digoxin is a complex agent in that its mode of action, inhibition of Na^+/K^+ -ATPase, affects multiple cellular processes, including several critical to cardiac myocyte function.¹ Digoxin is also extremely toxic—not surprising in view of its apparent role in nature as a toxin evolved by plants to kill marauding mammals. Cardiac glycosides bind to a specific high-affinity site on the extracytoplasmic face of the alpha subunit of Na^+/K^+ -ATPase, the enzymatic equivalent of the cellular sodium pump.¹ The affinity of the subunit for cardiac glycosides varies among species and among the three known mammalian subunit isoforms, each of which is encoded by a separate gene.¹

Cardiac glycoside binding to and inhibition of the Na^+/K^+ -ATPase sodium pump are reversible and entropically driven. Under physiologic conditions, these drugs preferentially bind to the enzyme after phosphorylation of a beta-aspartate on the cytoplasmic face of the alpha subunit, thus stabilizing what is known as the E2P conformation.^{1,2} Extracellular K^+ promotes dephosphorylation at this site, resulting in a decrease in the cardiac glycoside binding affinity for the enzyme.² This action presumably explains why increased extracellular K^+ tends to reverse some manifestations of digitalis toxicity.

Positive Inotropic Effect

Cardiac glycosides increase the velocity and extent of shortening of cardiac muscle, thereby resulting in an upward and leftward shift of the ventricular function curve (Frank-Starling) relating cardiac performance to filling volume or pressure. This process occurs in normal as well as failing myocardium and in atrial as well as ventricular muscle. The effect appears to be sustained for periods of weeks or months without evidence of desensitization or tolerance.³

The positive inotropic effect is due to an increase in the availability of cytosolic Ca^{2+} during systole, thus increasing the velocity and extent of sarcomere shortening. The increase in intracellular $[\text{Ca}^{2+}]$ is a consequence of cardiac glycoside-induced inhibition of sarcolemmal Na^+/K^+ -ATPase.^{1,2} Inhibition of Na^+/K^+ -ATPase causes an increase in intracellular Na^+ , which is then exchanged for extracellular Ca^{2+} through the $\text{Na}^+/\text{Ca}^{2+}$ exchanger. The net effect of these adjustments is to increase intracellular Ca^{2+} during systole, which increases systolic function.

In part because cardiac glycosides produce an increase in contractile function without increasing the heart rate, the positive inotropic effects are more energetically efficient than the effects of beta-adrenergic agonists and higher doses of phosphodiesterase inhibitors.⁴ This difference may be one of the reasons why low dose digoxin does not increase mortality in patients with HF.⁵

Antiadrenergic Properties

Na^+/K^+ -ATPase is involved in baroreflex afferent signaling and may be upregulated in the carotid sinus in HF.⁶ Decreased baroreflex control is one of the mechanisms responsible for an increase in generalized and cardiac adrenergic activity in HF.⁶ Inhibition of Na^+/K^+ -ATPase by ouabain modulates baroreflex function toward normal in animal models of HF,⁶ which is likely to be the mechanism by which cardiac glycosides inhibit adrenergic activity in HF.

Electrophysiologic Actions

Cardiac glycosides have complex electrophysiologic effects that are a combination of indirect, parasympathetic, and direct effects on specialized cardiac pacemaker and conduction tissues. At low to moderate therapeutic serum concentrations (0.5 to 1.9 ng/mL),

digoxin usually decreases automaticity and increases maximal diastolic resting membrane potential in atrial and atrioventricular nodal cells as a result of augmented vagal tone and decreased sympathetic nervous system activity. These effects are accompanied by prolongation of the effective refractory period and decreased atrioventricular nodal conduction velocity. At higher, toxic digoxin levels or in the presence of underlying disease, patients are susceptible to sinus bradycardia or arrest, prolongation of atrioventricular conduction, or heart block. At toxic levels, cardiac glycosides also can increase sympathetic nervous system activity, potentially contributing to the generation of arrhythmias.

Increased intracellular Ca^{2+} loading and increased sympathetic tone both contribute to an increased rate of spontaneous (phase 4) diastolic depolarization and also to delayed afterdepolarizations that may reach threshold and generate propagated action potentials. The combination of increased automaticity and depressed conduction in the His-Purkinje network predisposes the patient to development of arrhythmias, including ventricular tachycardia and fibrillation. Data from the Digitalis Investigation Group (DIG) Trial⁷ suggest that the increase in ventricular arrhythmia manifested in chronic HF as an increase in sudden death extends down to digoxin serum levels of 1.0 ng/mL, inasmuch as higher concentrations were associated with an increase in mortality.

Pharmacokinetics and Dosing

Orally administered digoxin is variably absorbed, depending on the preparation, and has a bioavailability of 60% to 80% when given orally. Digoxin is approximately 25% protein bound in plasma, has a large volume of distribution (4 to 7 liters/kg), and crosses both the blood-brain barrier and the placenta. Digoxin is eliminated primarily by renal mechanisms, both glomerular filtration and tubular secretion. Tubular excretion is through the energy-dependent membrane-bound efflux pump-transport enzyme, P-glycoprotein, which is modulated by many other drugs. Digoxin is largely excreted in the urine unchanged, with a clearance rate proportional to the glomerular filtration rate, which results in the excretion of approximately one third of body stores daily. The half-life for digoxin elimination of 36 to 48 hours in patients with normal or near-normal renal function permits once-daily or every-other-day dosing.⁸ In the presence of an elevated blood urea nitrogen/serum creatinine ratio (i.e., “prerenal azotemia”), digoxin clearance more closely parallels urea clearance, indicating that under these circumstances some of the drug filtered through the glomerulus undergoes tubular reabsorption.⁸ In patients with HF, increased cardiac output and renal blood flow in response to treatment with vasodilators or sympathomimetic agents may increase renal digoxin clearance, necessitating dosage adjustment.

Digoxin can be loaded at a dose of 0.75 to 1.25 mg orally (or intravenously at doses 25% lower) over a 24-hour period in three or four divided doses and then given at a maintenance dose, or a daily maintenance dose of 0.0625 to 0.25 mg/day orally can be started, depending on renal function, body size, and the presence or absence of coadministered drugs known to cause pharmacokinetic interactions. In the absence of loading doses, nearly steady-state blood levels are achieved in four to five half-lives, or approximately 1 week after initiation of maintenance therapy if normal renal function is present. If the drug is given intravenously, administration should be carried out over at least 15 minutes to avoid vasoconstrictor responses to a more rapid injection. Intramuscular digoxin is absorbed unpredictably, causes local pain, and is not recommended.

Patients with HF usually have a reduced volume of distribution and reduced renal function, and both may be influenced by other treatments and by the ebb and flow of HF. Although nomograms on digoxin dosing have been published, such nomograms should not be used in patients with HF because of the narrow therapeutic index and the unpredictability of the numerous factors that can alter digoxin pharmacokinetics. Instead, patients should be started on a dose as just described and trough levels (see later) measured 1 to 2 weeks later and at frequent intervals (every 1 to 3 months) thereafter.

Drug Interactions with Digoxin

Numerous drugs interact with digoxin at multiple levels, including reduced renal tubular excretion by drugs inhibiting P-glycoprotein renal tubular transport,⁹ induction of gut P-glycoprotein, alterations in gut flora by antibiotics causing less gut metabolism of digoxin before absorption, displacement from plasma protein-binding sites, or reduction in renal function. A partial list of these interactions is given in **Table e25-2**. Among these interactions are those involving drugs that are routinely used in patients with HF, including carvedilol and amiodarone, in the presence of which digoxin doses should be lowered.

Therapeutic Drug Monitoring

Digoxin has an extremely low therapeutic index, and its use should be carefully monitored by determination of serum blood levels. The various clinical conditions and drug interactions that can alter digoxin's pharmacokinetics also are reflected in the serum digoxin level. As discussed earlier, on the basis of the dose range of the positive inotropic effects,¹⁰ the neurohormonal inhibition effects,¹¹ and the DIG trial mortality data,⁷ the optimal trough digoxin serum level is 0.5 to 1.0 ng/mL. This concentration range also is the one that should be used to control the ventricular rate response to atrial fibrillation in patients with HF, particularly because digoxin is not a very effective agent in this regard in the setting of high amounts of adrenergic activity.¹² Blood samples for measurement of serum digoxin levels should be taken at least 6 to 8 hours after the last digoxin dose, and patients should be instructed to take their digoxin in the evening so that any level determined during the day is a trough measurement.

TABLE e25-2 Partial List of Drugs Interacting with Digoxin

DRUG	EFFECT ON SERUM LEVEL	MECHANISM
Amiodarone	Increases	??Renal clearance
Verapamil	Increases	?Renal clearance
Nifedipine	Increases	?Renal clearance
Diltiazem	Increases	?Renal clearance
Quinidine	Increases	Displacement of protein binding, ?renal clearance
Propafenone	Increases	?Renal clearance
Captopril	? Increases	? Renal clearance
Carvedilol	Increases	?Oral bioavailability
Spironolactone	Increases	?Renal clearance
Amiloride	Increases	?Renal clearance
Triamterene	Increases	?Renal clearance
Salbutamol	Decreases	Unknown
Macrolide antibiotics	Increases	Altered gut flora, ?renal clearance
Tetracycline	Increases	Altered gut flora
Indomethacin	Increases	?Renal clearance
Alprazolam	Increases	??Renal clearance
Itraconazole	Increases	?Renal clearance
Rifampin	Decreases	Induction of gut P-glycoprotein
Sucralfate	Decreases	Decreased gut absorption
Cholestyramine	Decreases	Decreased gut absorption
Cyclosporine	Increases	?Renal clearance
St. John's wort	Increases	?Renal clearance

Digitalis Toxicity

In patients with HF, overt clinical toxicity tends to emerge at serum concentrations greater than 2.0 ng/mL, but substantial overlap in serum levels exists among patients exhibiting symptoms and signs of toxicity and those with no clinical evidence of intoxication. Disturbances in cardiac impulse formation, conduction, or both are the hallmarks of digitalis toxicity. Among the common electrocardiographic manifestations are ectopic beats of atrioventricular junctional or ventricular origin, first-degree atrioventricular block, an excessively slow ventricular rate response to atrial fibrillation, or an accelerated atrioventricular junctional pacemaker. These manifestations may require only dosage adjustment and monitoring. Sinus bradycardia, sinoatrial arrest or exit block, and second- or third-degree atrioventricular conduction delay often respond to atropine, but temporary ventricular pacing is sometimes necessary and should be available.

Management

Oral potassium administration often is useful for atrial, atrioventricular junctional, or ventricular ectopic rhythms, even when the serum potassium is in the normal range, unless high-grade atrioventricular block also is present. However, the potassium level must be monitored carefully to avoid hyperkalemia, especially in patients with renal failure. Magnesium may be useful in patients with atrial fibrillation in an accessory pathway in whom digoxin administration has facilitated a rapid accessory pathway-mediated ventricular response; again, careful monitoring is required to avoid hypermagnesemia.¹³ Neurologic or gastrointestinal complaints also can be manifestations of digitalis toxicity. Occasionally, gynecomastia results from digoxin administration, apparently because of the similarity of the glycoside structure to that of estrogens.

Antidigoxin Immunotherapy

Potentially life-threatening digoxin or digitoxin toxicity can be reversed by antidigoxin immunotherapy. Purified Fab fragments from digoxin specific antisera are available at most poison control centers and larger hospitals in North America and Europe. Clinical experience in adults and children has established the effectiveness and safety of antidigoxin Fab in treating life-threatening digoxin toxicity, including cases of massive ingestion with suicidal intent.¹⁴ Doses of Fab are calculated by using a simple formula based on either the estimated dose of drug ingested or the total body digoxin burden and are administered intravenously in saline over a period of 30 to 60 minutes.

In the year 2001 a new era of implantable device therapies for the management of heart failure was initiated with U.S. Food and Drug Administration (FDA) approval of the first device for cardiac resynchronization therapy (CRT). Over the subsequent few years, implantable cardioverter-defibrillators (ICDs) and combined CRT-ICD devices were also approved by the FDA for the management of heart failure. ICDs became indicated for the primary prevention of all-cause mortality through a reduction in the incidence of sudden cardiac death (SCD) in patients with heart failure and reduced ejection fractions. Combined CRT-ICD devices were shown to reduce morbidity and mortality in heart failure patients with a reduced ejection fraction (HFrEF) and ventricular dyssynchrony, with a suggestion of additive benefit over a CRT device alone. In acknowledgement of the evidence-based benefits of these devices, the 2005 update of the American College of Cardiology/American Heart Association (ACC/AHA) heart failure guideline strongly supported, with class I indications, the use of ICD and/or CRT devices for the management of eligible heart failure patients¹; these indications were updated in 2013² (see Table 26G-1).

In addition to these therapeutic devices, implantable devices that monitor physiologic parameters such as patients' activity level, heart rate variability (HRV), intrathoracic impedance, and/or hemodynamics have been developed. In some cases these data are already available in currently implantable CRT and ICD devices. The usefulness of such device-based diagnostic or monitoring information is unknown and currently under investigation. This chapter reviews the use of CRT and ICDs for the management of heart failure and discusses the potential usefulness of implantable heart failure monitoring devices. Medical management of heart failure is discussed in Chapters 25 and 27.

VENTRICULAR DYSSYNCHRONY: THE TARGET OF CARDIAC RESYNCHRONIZATION THERAPY

Several conduction abnormalities are commonly seen in association with chronic heart failure. Among these are abnormalities in ventricular conduction, such as bundle branch blocks, that alter the timing and pattern of ventricular contraction such that the already failing heart is placed at further mechanical disadvantage. These ventricular conduction delays produce suboptimal ventricular filling, a reduction in left ventricular contractility, prolonged duration of mitral regurgitation, and paradoxical septal wall motion.^{3,4} Taken

together, these mechanical manifestations of altered ventricular conduction have been termed *ventricular dyssynchrony*. Ventricular dyssynchrony has been defined by a prolonged QRS duration, generally greater than 120 milliseconds, on the surface electrocardiogram. By this definition, approximately a third of patients with systolic heart failure have ventricular dyssynchrony. In addition to reducing the ability of the failing heart to eject blood, ventricular dyssynchrony has also been associated with increased mortality in heart failure patients.^{3,4}

Ventricular dyssynchrony may now be addressed with pacing therapy through the implantation of pacing leads in both the right and left ventricles. This form of pacing therapy has come to be known as CRT. Favorable single-case experience with CRT in the mid-1990s led to small observational studies evaluating the acute effects of CRT on hemodynamics and other measures of cardiac performance.⁵ These studies provided additional proof of concept supporting the use of CRT. Several uncontrolled or unblinded studies soon followed to further evaluate the acute and longer-term effects of CRT on clinical status in heart failure patients.⁵ The results of these trials were equally encouraging, with patients demonstrating consistent, sustained improvement in exercise tolerance, quality of life, and New York Heart Association (NYHA) functional class. Finally, large-scale randomized controlled trials confirmed the beneficial effects of CRT on functional status and outcomes, thereby leading to the initial indications for this therapy. More recent trials have both expanded and also begun to limit the indications for CRT. Ongoing trials are exploring additional potential indications for CRT.

Randomized Controlled Trials of Cardiac Resynchronization Therapy in Patients with New York Heart Association Class III and IV Heart Failure

More than 4000 patients have been evaluated in randomized controlled trials of CRT for NYHA functional class III and IV heart failure. The following randomized controlled trials are considered among the landmark studies of CRT in this patient population: the MUSTIC (Multisite Stimulation in Cardiomyopathy) studies,^{6,7} the MIRACLE (Multicenter InSync Randomized Clinical Evaluation) trial,^{8,9} the MIRACLE ICD trial,¹⁰ the CONTAK CD trial,¹¹ the CARE-HF (Cardiac Resynchronization in Heart Failure) trial,^{12,13} and the COMPANION (Comparison of Medical Therapy, Pacing and Defibrillation in Heart

Failure) trial.^{14,15} To understand the clinical benefits, risks, and limitations of CRT with or without an ICD, these studies are reviewed.

Multisite Stimulation in Cardiomyopathy Trials

The MUSTIC trials were designed to evaluate the safety and efficacy of CRT in patients with advanced heart failure, ventricular dyssynchrony, and either normal sinus rhythm⁶ or atrial fibrillation.⁷ They represent the first randomized single-blind trials of CRT for heart failure. The first study involved 58 randomized patients with NYHA class III heart failure, normal sinus rhythm, and a QRS duration of at least 150 milliseconds. All patients had a CRT device implanted and, after a run-in period, were randomly assigned to either active pacing or no pacing. After 12 weeks, patients crossed over and remained in the alternate study assignment for 12 weeks. The second MUSTIC study included fewer patients (only 37 completers) with atrial fibrillation and a slow ventricular rate (either spontaneously or as a result of radiofrequency ablation). A VVIR biventricular pacemaker and leads for each ventricle were implanted and the same randomization procedure described above was applied; however, biventricular VVIR pacing and single-site right ventricular VVIR pacing (rather than no pacing) were compared in this group of patients with atrial fibrillation.

The primary endpoints of the MUSTIC trials were exercise tolerance as assessed by measurement of peak VO_2 or the 6-minute hall walk test and quality of life as determined by using the Minnesota Living with Heart Failure (MLWHF) questionnaire. Secondary endpoints included rehospitalization and/or modifications in drug therapy for worsening heart failure. Results from the normal sinus rhythm arm of the MUSTIC trials provided strong evidence of benefit. The mean distance walked in 6 minutes was 23% greater with CRT than without CRT ($P < 0.001$). Significant improvement was also seen in quality of life and NYHA functional class ranking. In addition, fewer hospitalizations occurred during active resynchronization therapy. The atrial fibrillation cohort evaluated in the MUSTIC trials demonstrated similar improvements, although the magnitude of benefit was slightly less.

Multicenter InSync Randomized Clinical Evaluation

MIRACLE was the first prospective, randomized, double-blind, parallel-controlled clinical trial designed to evaluate the benefits of CRT.^{8,9} Primary endpoints were NYHA class, quality-of-life score (using the MLWHF questionnaire), and 6-minute hall walk distance. Secondary endpoints included assessment of a composite clinical response, cardiopulmonary exercise performance, cardiac structure and function, a variety of measures of worsening heart failure, and combined morbidity and mortality.

The MIRACLE trial was conducted between 1998 and 2000. It included 453 patients with moderate to severe symptoms of heart failure associated with a left ventricular ejection fraction (LVEF) of 35% or less and a QRS duration of at least 130 milliseconds. Patients were randomly assigned (double-blind) to CRT ($n = 228$) or to a control group ($n = 225$) for 6 months while conventional therapy for heart failure was maintained. When compared with the control group, patients randomly assigned to CRT demonstrated a significant improvement in quality-of-life score (-18.0 versus -9.0 points, $P = 0.001$), 6-minute walk distance ($+39$ versus $+10$ meters, $P = 0.005$), NYHA functional class ranking (-1.0 versus 0.0 class, $P < 0.001$), treadmill exercise time ($+81$ versus $+19$ seconds, $P = 0.001$), peak VO_2 ($+1.1$ versus 0.1 mL/kg/min, $P < 0.01$), and LVEF ($+4.6\%$ versus -0.2% , $P < 0.001$). Patients assigned to CRT demonstrated highly significant improvement in a composite clinical heart failure response endpoint relative to control subjects, thus suggesting an overall improvement in clinical heart failure status (Fig. 26-1). In addition, when compared with the control group, fewer patients in the CRT group required hospitalization (8% versus 15%) or intravenous medications (7% versus 15%) for the treatment of worsening heart failure (both $P < 0.05$). In the resynchronization group, the 50% reduction in hospitalization was accompanied by a significant reduction in length of stay, which resulted in a 77% decrease in total days hospitalized over a period of 6 months in comparison to the control group. The major

FIGURE 26-1 Effect of CRT on a composite clinical response endpoint in the MIRACLE trial. Worsened indicates that the patient dies, is hospitalized because of or associated with deteriorating heart failure, or demonstrates worsening in NYHA class at last observation carried forward (LOCF) or moderate to marked worsening of patient global assessment score at LOCF. Improved indicates that the patient has not worsened (as defined above) and demonstrates improvement in NYHA class at LOCF and/or moderate to marked improvement in patient global assessment score at LOCF. Unchanged indicates that the patient is neither improved nor worsened. $P < 0.001$ for chi-square analysis. (Modified from Abraham WT, Fisher WG, Smith AL, et al, for the Multicenter InSync Randomized Clinical Evaluation [MIRACLE] Investigators and Coordinators: Double-blind, randomized controlled trial of cardiac resynchronization in chronic heart failure. *N Engl J Med* 346:1845, 2002.)

limitation of the therapy was unsuccessful implantation of the device in 8% of patients. The results of this trial led to U.S. FDA approval of the InSync system in August 2001, the first approved CRT system in the United States, thus allowing the introduction of CRT into clinical practice.

The MIRACLE trial also provided persuasive evidence supporting the occurrence of reverse left ventricular remodeling with chronic CRT. In the MIRACLE trial, serial Doppler echocardiograms were obtained at baseline and at 3 and 6 months in a subset of 323 patients. CRT for 6 months was associated with reduced end-diastolic and end-systolic volumes (both $P < 0.001$), reduced left ventricular mass ($P < 0.01$), increased ejection fraction ($P < 0.001$), reduced mitral regurgitant blood flow ($P < 0.001$), and improved myocardial performance index ($P < 0.001$) in comparison to the control group. These effects are similar to those noted with beta blockade for heart failure but were seen in the MIRACLE trial in patients already receiving beta blocker therapy.

Multicenter InSync Implantable Cardioverter Defibrillator Randomized Clinical Evaluation

The MIRACLE ICD study was designed to be almost identical to the MIRACLE trial. MIRACLE ICD was a prospective, multicenter, randomized, double-blind, parallel-controlled clinical trial intended to assess the safety and efficacy of a combined CRT-ICD system in patients with dilated cardiomyopathy (LVEF $\leq 35\%$, left ventricular end-diastolic dimension [LVEDD] ≥ 55 mm), NYHA class III or IV heart failure, ventricular dyssynchrony (QRS ≥ 130 milliseconds), and an indication for an ICD.¹⁰ Primary and secondary efficacy measures were essentially the same as those evaluated in the MIRACLE trial but also included measures of ICD function.

Of 369 patients receiving devices and randomly assigned, 182 were controls (ICD activated, CRT inactive) and 187 were in the resynchronization group (ICD activated, CRT active). At 6 months, patients assigned to active CRT had a greater improvement in median quality-of-life score (-17.5 versus -11.0 , $P = 0.02$) and functional class (-1 versus 0 , $P = 0.007$) than did controls but were no different from controls in the change in distance walked in 6 minutes (55 versus 53 meters, $P = 0.36$). Peak oxygen consumption increased by 1.1 mL/kg/min in the resynchronization group versus 0.1 mL/kg/min in controls ($P = 0.04$), whereas the duration of treadmill exercise increased by 56 seconds in the CRT group and decreased by 11 seconds in controls ($P = 0.0006$). The magnitude of improvement was comparable to that seen in the MIRACLE trial, thus suggesting that heart failure patients with an indication for an ICD benefit as much from CRT as do patients without an indication for an ICD. The combined CRT-ICD device used

in this study was approved by the FDA in June 2002 for use in patients with NYHA class III and IV systolic heart failure, ventricular dyssynchrony, and an indication for an ICD.

CONTAK CD

The CONTAK CD trial enrolled 581 symptomatic heart failure patients with ventricular dyssynchrony and malignant ventricular tachyarrhythmias, all of whom were candidates for an ICD.¹¹ Following unsuccessful implant attempts and withdrawals, 490 patients were available for analysis. The study did not meet its primary endpoint of a reduction in disease progression, as defined by a composite endpoint of hospitalization for heart failure, all-cause mortality, and ventricular arrhythmia requiring defibrillator therapies, although the trends were in a direction favoring improved outcomes with CRT. However, the CONTAK CD trial did demonstrate statistically significant improvements in peak oxygen uptake and quality of life in the resynchronization group in comparison to control subjects, although quality of life was improved only in NYHA class III and IV patients without right bundle branch block. Left ventricular dimensions were also reduced, and LVEFs increased, as seen in other trials of CRT. Importantly, the improvement noted in peak Vo_2 with cardiac resynchronization was again comparable to that observed in the MIRACLE trial. Improvements in NYHA functional class were not observed in this study. The CONTAK CD device was approved by the FDA in May 2002 for use in patients with NYHA class III and IV systolic heart failure, ventricular dyssynchrony, and an indication for an ICD.

Cardiac Resynchronization in Heart Failure Trial

The CARE-HF trial was designed to evaluate the effects of resynchronization therapy without an ICD on morbidity and mortality in patients with NYHA class III or IV heart failure and ventricular dyssynchrony.^{12,13} In this trial, 819 patients with an LVEF of 35% or less and ventricular dyssynchrony, defined as a QRS duration of 150 milliseconds or greater or a QRS duration between 120 and 150 milliseconds with echocardiographic evidence of dyssynchrony, were enrolled in this randomized, unblinded, controlled trial and monitored for an average of 29.4 months. Of these, 404 patients were randomly assigned to receive optimal medical therapy alone and 409 patients to optimal medical therapy plus resynchronization therapy. The risk for death from any cause or unplanned hospitalization for a major cardiac event, the primary endpoint analyzed as time to the first event, was significantly reduced by 37% in the treatment group versus control subjects (hazard ratio [HR], 0.63; 95% confidence interval [CI], 0.51 to 0.77; $P < 0.001$). In the CRT group, 82 patients (20%) died during follow-up as opposed to 120 patients (30%) in the medical group—a significant 36% reduction in all-cause mortality with resynchronization therapy (HR, 0.64; 95% CI, 0.48 to 0.85; $P < 0.002$; Fig. 26-2). Resynchronization therapy also significantly reduced the risk for unplanned hospitalization for a major cardiac event by 39%, all-cause mortality plus hospitalization for heart failure by 46%, and hospitalization for heart failure by 52%.

Comparison of Medical Therapy, Pacing, and Defibrillation for Heart Failure

Begun in early 2000, COMPANION was a multicenter, prospective, randomized, controlled clinical trial designed to compare drug therapy alone with drug therapy in combination with cardiac resynchronization in patients with dilated cardiomyopathy, an intraventricular conduction defect, NYHA class III or IV heart failure, and no indication for a device.^{14,15} The COMPANION trial randomly assigned 1520 patients to one of three treatment groups in a 1:2:2 allocation—group I (308 patients) received optimal medical care only, group II (617 patients) received optimal medical care and the Guidant CONTAK TR (biventricular pulse generator), and group III (595 patients) received optimal medical care and the CONTAK CD (combined heart failure/bradycardia/tachycardia device). The primary endpoint of the COMPANION trial was a composite of all-cause mortality and all-cause hospitalization, measured as time to the first event beginning from the time of randomization. Secondary endpoints included all-cause mortality and a variety of measures of

Number at risk

CRT	409	376	351	213	89	8
Medical therapy	404	365	321	192	71	5

(Modified from Cleland JGF, Daubert J-C, Erdmann E, et al, for the Cardiac Resynchronization-Heart Failure (CARE-HF) Study Investigators: The effect of cardiac resynchronization on morbidity and mortality in heart failure. *N Engl J Med* 352:1539, 2005.)

CRT vs. OPT: RR = 24%, $p = 0.060$ (Critical boundary = 0.014)

CRT-D vs. OPT: RR = 36%, $p = 0.003$ (Critical boundary = 0.022)

FIGURE 26-3 Kaplan-Meier estimates of the time to death from any cause in patients randomly assigned to optimal medical therapy (OPT) alone, OPT with CRT alone, or OPT with a combined CRT-ICD device in the COMPANION trial. AR = absolute risk; RR = relative risk. (Modified from Bristow MR, Saxon LA, Boehmer J, et al: Cardiac-resynchronization therapy with or without an implantable defibrillator in advanced chronic heart failure. *N Engl J Med* 350:2140, 2004.)

cardiovascular morbidity. When compared with optimal medical therapy alone, the combined endpoint of mortality or hospitalization for heart failure was reduced by 35% in patients receiving CRT and by 40% in patients receiving CRT-ICD (both $P < 0.001$). For the mortality endpoint alone, CRT patients had a 24% reduction in risk ($P = 0.060$) and CRT-ICD patients experienced a 36% reduction in risk ($P < 0.003$) when compared with optimal medical therapy (Fig. 26-3). The COMPANION trial confirmed the results of earlier resynchronization therapy trials in improving symptoms, exercise tolerance, and quality of life in heart failure patients with ventricular dyssynchrony. In addition, it showed for the first time the impact of CRT-ICD in reducing all-cause mortality and suggested incremental benefit from combined device therapies. These trials in patients with NYHA class III and IV heart failure established the initial 2005 guideline recommendation for CRT: “Patients with LVEF less than or equal

to 35%, sinus rhythm, and NYHA functional class III or ambulatory class IV symptoms despite recommended optimal medical therapy and who have cardiac dyssynchrony, which is currently defined as a QRS greater than or equal to 0.120 seconds, should receive CRT, with or without an ICD, unless contraindicated (level of evidence: A).¹⁹ These guidelines have recently been updated and are discussed later under the indications for CRT.

More recent clinical trials of CRT have focused on delaying progression of heart failure in asymptomatic or less symptomatic patients. The MIRACLE ICD II trial suggested such a benefit in a small cohort of NYHA class II subjects,¹⁶ which led to subsequent large-scale trials in this population.

Randomized Controlled Trials of Cardiac Resynchronization Therapy in Patients with New York Heart Association Class I and II Heart Failure

More than 4500 patients have been evaluated in randomized controlled trials of CRT for those with NYHA functional class I and II heart failure. The following randomized controlled trials are considered to be among the landmark studies of CRT in this patient population: the REVERSE (Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction) trial,^{17,18} MADIT-CRT (Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy),^{19,20} and RAFT (Resynchronization/defibrillation for Ambulatory Heart Failure Trial).²¹

Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction Trial

The REVERSE trial was a randomized, double-blind, controlled trial designed to address the benefit of CRT versus optimal medical therapy alone on heart failure morbidity in patients with mild heart failure.^{17,18} In this trial, 610 patients with NYHA class I and II heart failure, a QRS duration of 120 milliseconds or longer, an LVEF of 40% or lower, and an LVEDD of 55 mm or greater were randomly assigned. All patients received a CRT device with or without an ICD; 191 were assigned to the control group of optimal medical therapy alone (CRT off) and 419 to the CRT group combined with optimal medical therapy. The primary endpoint was a clinical composite heart failure score. Because the goal of the study was to determine the effect of CRT in preventing disease progression, a “worsened” status was considered a negative outcome.

Even though the percentage of subjects whose clinical composite response endpoint worsened was not significantly reduced in the CRT group versus control subjects (16% versus 21%, $P = 0.10$), a significant benefit of CRT was noted in improvement in ventricular structure and function and in heart failure morbidity, with a 53% relative risk reduction in the time to first heart failure hospitalization (HR, 0.47; $P = 0.03$). Thus REVERSE was the first large randomized, multicenter trial to demonstrate the potential for CRT to slow progression of disease through reverse remodeling in patients with NYHA class I and II heart failure and ventricular dyssynchrony.

Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy

MADIT-CRT was a multicenter, randomized clinical trial designed to address the potential survival and morbidity benefit of CRT in patients with NYHA class I and II heart failure by assessing the reduction in risk for death and nonfatal heart failure events in this population.¹⁹ Prophylactic CRT combined with an ICD was compared with an ICD alone in 1820 patients with an LVEF of 30% or lower, QRS duration of 130 milliseconds or longer, and either an ischemic (class I patients) or any (class II patients) cause. The study was not blinded in that the treating physicians were aware of the study group assignments.

During the average follow-up of 2.4 years, the primary endpoint of death from any cause or a nonfatal heart failure event occurred in 17.2% of the CRT-ICD group versus 25.2% of the ICD-only group, a relative risk reduction of 34% (HR, 0.66; 95% CI, 0.52 to 0.84; $P = 0.001$) (Fig. 26-4). This significant benefit was driven by a 41% reduction in

FIGURE 26-4 Kaplan-Meier estimates of the probability of survival free of heart failure. There was a significant difference in the estimate of survival free of heart failure between the group that received CRT-ICD and the group that received an ICD only (unadjusted $P < 0.001$ by the log-rank test). (Modified from Moss AJ, Hall WJ, Cannom DS, et al: Cardiac resynchronization therapy for the prevention of heart failure events. *N Engl J Med* 361:1329, 2009.)

heart failure events (13.9% versus 22.8%; HR, 0.59; 95% CI, 0.47 to 0.74; $P < 0.001$). In terms of prespecified subgroups, both the ischemic and nonischemic groups showed benefit with CRT; however, greater benefit was noted in women than in men and in patients with a QRS duration of 150 milliseconds or longer. Another factor predicting CRT responsiveness in this trial was QRS morphology, with patients benefiting most having left bundle branch block (LBBB).²² MADIT-CRT led the FDA to expand the indication for CRT to NYHA class II or ischemic class I patients with an LVEF of less than 30%, a QRS duration longer than 130 milliseconds, and LBBB for the devices evaluated in this study.

Resynchronization/defibrillation for Ambulatory Heart Failure Trial

RAFT differed from the REVERSE trial and MADIT-CRT in that initially, patients in NYHA class II and III were included. However, after data from the CARE-HF trial showed a clear reduction in mortality for patients with NYHA class III heart failure, the protocol was revised to include only patients with NYHA class II. Importantly, RAFT was the first to show a mortality benefit of combined CRT-ICD over an ICD alone and a reduction in mortality with the addition of CRT in patients with NYHA class II heart failure.²¹ The primary outcome of all-cause mortality or hospitalization for heart failure occurred in 40% and 33% of the ICD and CRT-ICD groups, respectively, with a significant delay to time of occurrence of the primary outcome in the CRT-ICD group. Overall, 23.5% of the patients died. The 5-year actuarial death rate was lower (28.6% versus 34.6%) and the time until death was longer in the CRT-ICD patients than in the ICD group. On the basis of these results, 14 patients would need to be treated with a CRT-ICD for 5 years to prevent one death versus treatment with an ICD alone. These benefits were at the expense of an increased rate of procedure-related adverse events. Nevertheless, the results from RAFT and REVERSE resulted in the FDA expanding the indication for certain CRT devices to include patients with mildly symptomatic heart failure (NYHA class II), an LVEF of 30% or lower, LBBB, and a QRS duration of 130 milliseconds or longer.

Indications for Cardiac Resynchronization Therapy in Patients with Heart Failure

Since the original 2005 guideline recommendation for CRT, indications for CRT have been expanded to less symptomatic patients but also limited to some extent on the basis of QRS morphology and/or QRS duration.²³ Current guideline recommendations define ventricular dyssynchrony by QRS duration. Although echocardiography

appears to be a promising way to define ventricular dyssynchrony, the PROSPECT (Predictors of Response to Cardiac Resynchronization Therapy) trial did not support the use of echocardiographic measures of dyssynchrony as selection criteria for CRT in patients with QRS durations of 120 milliseconds or longer.^{24,25} Subgroup analyses from REVERSE, MADIT-CRT, and RAFT suggested that patients with QRS durations of 150 milliseconds or longer and/or those with LBBB morphology benefit most from CRT. Based on these observations, recommendations for the use of CRT were substantially revised in 2012 (see Table 26G-1).²³

According to these new CRT guidelines, indications for CRT include patients who have an LVEF of 35% or less, sinus rhythm, LBBB with a QRS duration of 120 milliseconds or longer, and NYHA class II, III, or ambulatory IV symptoms while receiving optimal medical treatment. Although the level of indication is somewhat stronger for patients fulfilling these criteria with a QRS duration of 150 milliseconds or greater, CRT should generally be offered to all heart failure patients with a reduced ejection fraction and LBBB. In patients with more advanced heart failure (i.e., NYHA class III and ambulatory class IV patients), those fulfilling the aforementioned criteria with a QRS duration of at least 150 milliseconds and non-LBBB morphology should also be considered for CRT.

Limitations of Cardiac Resynchronization Therapy

The success rate for placement of a transvenous cardiac resynchronization system has ranged from approximately 88% to 92% in clinical trials, although in contemporary clinical experience it is as high as 97% to 98% in some centers (e.g., the Ohio State University experience). Thus some patients undergoing an implant procedure will not receive a functioning system if this approach is used. Implant-related complications are similar to those seen with standard pacemakers and defibrillators, with the additional risk of dissection or perforation of the coronary sinus. This is a rare event but may lead to substantial morbidity and even mortality in heart failure patients.

Despite the results of randomized controlled CRT trials, some patients do not respond to this therapy. The nonresponder rate for CRT appears to be approximately 25%, a rate that is similar to the nonresponder rate for heart failure drug therapies. A variety of factors have been proposed to contribute to the nonresponder rate associated with CRT, including suboptimal left ventricular lead placement, suboptimal AV and VV timing, ventricular scar, and progression of heart failure disease.

Future Directions in Cardiac Resynchronization Therapy

Currently, CRT is being evaluated in patients with narrow QRS durations and also in those with mild reductions in LVEF (LVEF of 36% to 50%). The largest randomized controlled trial of CRT in patients with narrow QRS durations was the Echo-CRT (Echocardiographic-guided CRT) trial.²⁶ Echo-CRT was an investigator-initiated, international, multicenter, prospective, double-blind, randomized controlled clinical trial. It enrolled patients with moderate to severe symptoms of systolic heart failure, a narrow QRS duration of less than 130 milliseconds, and echocardiographic evidence of cardiac dyssynchrony. Patients received all the usual therapies for heart failure, including an ICD, and were randomly assigned to receive CRT or no CRT. The trial was stopped early for futility by the data and safety monitoring board. At study closure, 809 patients were randomly assigned to CRT = ON or CRT = OFF and observed for an average of 19.6 months. The primary outcome of death from any cause or first hospitalization for worsening heart failure occurred in 116 of 404 CRT patients versus 102 of 405 control patients (28.7% versus 25.2%, $P = \text{NS}$) and did not demonstrate a benefit of CRT in the study population. More patients died in the CRT group, but the number of deaths was too small for the findings to be definitive. The MIRACLE-EF trial (www.clinicaltrials.gov; identifier NCT01735916) is evaluating the effects of CRT on morbidity and mortality in patients with NYHA class II and III heart failure

and an LVEF of 36% to 50%, a QRS duration of less than 130 milliseconds, and a LBBB.

SUDDEN CARDIAC DEATH IN PATIENTS WITH HEART FAILURE

Patients with heart failure and left ventricular systolic dysfunction are at increased risk for SCD (see also Chapter 39).²⁷⁻²⁹ SCD is the leading cause of mortality in patients with heart failure and occurs at a rate six to nine times that seen in the general population. Given this high incidence of SCD in patients with heart failure, it was logical to hypothesize that an ICD used as prophylactic therapy would reduce total mortality by decreasing the incidence of SCD. A series of studies have tested this hypothesis.

Randomized Controlled Trials of Implantable Cardioverter-Defibrillators for Heart Failure

Several early studies supported the benefit of prophylactic ICD implantation, but none of them proved so conclusively. Landmark trials establishing a role for ICDs as primary prevention of mortality in heart failure patients are MADIT II (Multicenter Automatic Defibrillator Implantation Trial II),³⁰ the DEFINITE (Prophylactic Defibrillator Implantation in Patients with Nonischemic Dilated Cardiomyopathy) trial,³¹ and the National Institutes of Health-sponsored SCD-HeFT (Sudden Cardiac Death–Heart Failure Trial).³²

Multicenter Automatic Defibrillator Implantation Trial II

MADIT II, a randomized controlled trial, was prospectively designed and powered to assess the survival benefit of ICDs in a population of post-myocardial infarction patients with reduced ejection fractions (<30%).³⁰ Importantly, this trial included no arrhythmic markers for inclusion, such as nonsustained or inducible ventricular tachycardia. A total of 1232 patients were randomly assigned in a 3:2 ratio to receive an ICD (742 patients) or conventional medical therapy (490 patients). During an average follow-up of 20 months, all-cause mortality rates were 19.8% in the conventional therapy arm and 14.2% in the ICD group (31% relative risk reduction, $P = 0.016$) (Fig. 26-5). The effect of ICD therapy on survival was similar in subgroup analyses stratified according to age, sex, ejection fraction, NYHA class, and the QRS interval. Moreover, beta blockers were used by 72% of these patients, who were well balanced between the ICD and conventional therapy groups. Of note, most of the patients enrolled into MADIT II were classified as NYHA class II or III. Class IV patients were excluded and the class I cohort was relatively small. The average LVEF was 23%. The findings suggested that heart failure patients with mild to moderate symptoms and moderate to severe reductions in LVEF may benefit the most from a prophylactic ICD. Moreover, the survival benefit observed in MADIT II began approximately 9 months after the device was implanted. This observation may be important when considering the timing of device placement in eligible patients.

Prophylactic Defibrillator Implantation in Patients with Nonischemic Dilated Cardiomyopathy Trial

Although MADIT II enrolled exclusively post-myocardial infarction patients with an ischemic cause of left ventricular systolic dysfunction and heart failure, DEFINITE was the first randomized trial of primary prevention therapy with an ICD in patients with nonischemic cardiomyopathy.³¹ Such patients also exhibit high rates of SCD; however, until recently there has been little consensus regarding the management of risk for SCD in such patients. This may be due in part to limitations in objective risk assessment in that no invasive or noninvasive testing procedure has been shown to accurately determine which nonischemic heart failure patient is likely to die suddenly. Also clouding the picture were older observations suggesting that the prophylactic administration of an antiarrhythmic agent, amiodarone, might prolong survival in patients with nonischemic cardiomyopathy.

FIGURE 26-5 Kaplan-Meier estimates of survival in patients randomly assigned to treatment with an ICD or conventional medical therapy in MADIT II. The relative risk reduction was 31% with the ICD ($P = 0.007$ by log-rank test). (Modified from Moss AJ, Hall WJ, Cannom DS, et al: Cardiac resynchronization therapy for the prevention of heart failure events. *N Engl J Med* 361:1329, 2009.)

The DEFINITE trial was a prospective evaluation of 458 patients with nonischemic dilated cardiomyopathy. Entry criteria included an ejection fraction of 35% or less, a history of symptomatic heart failure, and the presence of ambient arrhythmia defined as an episode of nonsustained ventricular tachycardia or at least 10 premature ventricular contractions per 24-hour period during continuous ambulatory electrocardiographic monitoring. Two hundred twenty-nine patients were randomly assigned to each arm of the study and received either an ICD and standard medical therapy or standard medical therapy alone. Compliance with medical therapy was excellent and included an angiotensin-converting enzyme (ACE) inhibitor in 86% of the cohort and a beta blocker in 85%. The patients were monitored for a mean of 29.0 ± 14.4 months with a primary endpoint of all-cause mortality.

Sixty-eight deaths were reported in the DEFINITE trial, 28 in the ICD group and 40 in the standard therapy group. Implantation of an ICD yielded a nonsignificant 35% reduction in death from any cause (HR, 0.65; 95% CI, 0.40 to 1.06; $P = 0.08$) and significantly reduced the risk for sudden death by a remarkable 80% (HR, 0.20; 95% CI, 0.06 to 0.71; $P = 0.006$). In the subgroup of NYHA class III patients, all-cause mortality was significantly decreased in the ICD arm (HR, 0.37; 95% CI, 0.15 to 0.90; $P = 0.02$). Although this study was underpowered and did not reach statistical significance with respect to the primary endpoint of all-cause mortality for the entire randomly assigned cohort, the results demonstrated a strong trend toward a survival advantage for patients receiving an ICD.

Sudden Cardiac Death–Heart Failure Trial

The results of SCD-HeFT were published in 2005 and have had a substantial impact on current practice guidelines for ICDs.³¹ This landmark randomized controlled trial enrolled 2521 patients between 1997 and 2001. Patients with NYHA class II (70%) or III (30%) heart failure and reduced LVEF ($\leq 35\%$; mean, $\approx 25\%$) of either ischemic or nonischemic cause were eligible for the study. SCD-HeFT was a three-arm trial in which treatment with an ICD was compared with amiodarone and placebo. Thus SCD-HeFT addressed at least two important issues in heart failure management: (1) whether empiric amiodarone therapy saves lives in well-treated patients with NYHA class II and III heart failure and no arrhythmic indication for the drug and (2) whether a prophylactic ICD saves lives in such patients with heart failure from either an ischemic or nonischemic cause.

In SCD-HeFT, patients received standard heart failure therapy, if tolerated, which included an ACE inhibitor or angiotensin receptor blocker in 85%, beta blocker in 69%, and aldosterone antagonist in 19%, compatible with guideline recommendations at the time that the

FIGURE 26-6 Kaplan-Meier estimates of survival in patients randomly assigned to treatment with an ICD, conventional medical therapy, or conventional medical therapy plus amiodarone in SCD-HeFT. (Modified from Bardy GH, Lee KL, Mark DB, et al: Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. *N Engl J Med* 352:225, 2005.)

study was conducted. The median follow-up was 45.5 months. Importantly, the cohort was equally divided between ischemic and nonischemic causes of heart failure, thereby allowing an important subgroup analysis of these cohorts to be done.

Mortality rates in the ICD, amiodarone, and placebo groups were 17.1%, 24%, and 22.3% at 3 years and 28.9%, 34.1%, and 35.9%, respectively, at 5 years (Fig. 26-6). An ICD was associated with a statistically significant 23% reduction in all-cause mortality in comparison to placebo (HR, 0.77; 97.5% CI, 0.62 to 0.96; $P = 0.007$). Mortality in the amiodarone arm was not significantly different from that in the placebo arm across all subgroups (HR, 1.06; 97.5% CI, 0.86 to 1.30). Similar degrees of benefit with an ICD were noted in patients with ischemic (21% reduction in mortality) and nonischemic (27% reduction in mortality) heart failure, thus confirming the findings of MADIT II and DEFINITE, respectively. SCD-HeFT provides the most robust evidence to date supporting the prophylactic use of an ICD in patients with NYHA class II and III systolic heart failure.

Indications for Prophylactic Implantation of Implantable Cardioverter-Defibrillators in Patients with Heart Failure

The 2013 American College of Cardiology Foundation (ACCF)/AHA heart failure guidelines provided strong (level I) recommendations for prophylactic ICDs in HFrEF³²: “ICD therapy is recommended for primary prevention of SCD in selected patients with HFrEF at least 40 d post-MI with LVEF $< 35\%$ and NYHA class II or III symptoms on chronic guideline directed medical therapy, who are expected to live > 1 year (level of evidence: A) and ICD therapy is recommended for primary prevention of SCD in selected patients with HFrEF at least 40 d post-MI with LVEF $< 30\%$ and NYHA class I symptoms while receiving guideline directed medical therapy, who are expected to live > 1 year (level of evidence: B).” Of note in the context of this recommendation, a recent study showed the importance of ICD programming in minimizing inappropriate shocks and improving patient outcomes.³³ This trial demonstrated that programming of ICD therapies for tachyarrhythmias of 200 beats/min or higher or with a prolonged

delay in therapy for tachyarrhythmias of 170 beats/min or higher, as opposed to conventional programming, was associated with reductions in inappropriate therapy and all-cause mortality during an average follow-up of 1.4 years.

IMPLANTABLE DEVICES TO MONITOR HEART FAILURE

Device-Based Heart Failure Diagnostics

Implantable devices can provide substantial physiologic information about patients with heart failure. Such information may be useful in evaluating heart failure clinical status and/or in predicting episodes of heart failure decompensation. If these devices are reliable in the latter sense, use of this information may improve heart failure outcomes by reducing the risk for worsening heart failure. For example, many implantable CRT and ICD devices can provide information on atrial heart rate and rhythm, ventricular heart rate and rhythm, patient activity level, HRV, and in some cases intrathoracic impedance, which has been proposed as a measure of lung “wetness.” Many implantable devices record an activity trend, thereby providing an objective record of the number of hours per day that patients are physically active. The activity level may serve as a useful teaching and reinforcement tool to both the patient and family about the importance and level of activity. Because exercise intolerance is a manifestation of worsening heart failure, a decrease in a patient’s activity level may provide one objective clue to disease progression or decompensation.

HRV reflects the balance between sympathetic and parasympathetic nervous system activity in the heart; a decrease in HRV is a marker of increased sympathetic and decreased parasympathetic tone (see Chapter 89). A study by Adamson and colleagues³⁴ showed that HRV fell in the days to weeks leading to hospitalization for worsening heart failure, thus suggesting that decreases in HRV may predict episodes of worsening heart failure. Given our understanding of the changes in the neurohormonal milieu that occur as heart failure worsens, this approach to heart failure monitoring may ultimately prove useful.

Because most patients with decompensation exhibit pulmonary congestion because of elevated left ventricular filling pressure, indirect measurement of lung water or direct measurement of left ventricular filling pressure or its surrogate may be useful in managing heart failure patients on an outpatient basis. Implantable devices can monitor fluid status by assessing changes in intrathoracic impedance. In a small study of 33 patients, changes in intrathoracic impedance demonstrated the ability to predict hospitalization for decompensated heart failure 10 to 14 days in advance of the event.³⁵ A more recent and larger study confirmed this observation and demonstrated the superiority of intrathoracic impedance over daily weight monitoring in predicting worsening heart failure events.³⁶

Moreover, it appears that detection of changes in device-based heart failure diagnostic parameters by using an algorithm based on combined parameters can stratify patients into high-risk and low-risk subgroups. The PARTNERS-HF (Program to Access and Review Trending Information and Evaluate Correlation to Symptoms in Patients with Heart Failure) trial showed that patients with a positive combined heart failure device diagnostics score had a 5.5-fold

increased risk for heart failure hospitalization within a month of the assessment.³⁷ Despite this apparent usefulness of device-based diagnostics, to date no randomized controlled trial has demonstrated a reduction in heart failure hospitalization on the basis of this technology. One attempt to do so, DOT-HF (Diagnostic Outcome Trial in Heart Failure), demonstrated an expected increase in outpatient heart failure clinic visits and an unexpected increase in heart failure hospitalizations.³⁸

Implantable Hemodynamic Monitors

Finally, a new generation of even more sophisticated implantable monitoring devices is under investigation. These devices allow continuous or intermittent assessment of hemodynamics, generally focused on assessment of intracardiac or pulmonary artery pressure. Early observations supported the usefulness of these devices,³⁹⁻⁴² and a large randomized controlled outcomes trial confirmed these observations.

The CHAMPION (CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA class III Heart Failure Patients) trial randomly assigned 550 patients to two groups in which clinicians used daily measurement of pulmonary artery pressure in addition to standard of care (treatment group; $n = 270$) versus standard of care alone (control group; $n = 280$).^{43,44} A novel wireless pulmonary artery pressure monitoring system was used in this trial. The CHAMPION trial differed from previous studies of implantable hemodynamic monitors in that specific pressure targets and treatment algorithms were mandated by protocol to ensure adequate testing of the hypothesis. The primary endpoint of the trial was the rate of heart failure hospitalization over a period of 6 months, and long-term outcomes were also prospectively evaluated.

Over a 6-month period, significantly fewer heart failure hospitalizations occurred in the treatment group than in the control group (83 in the treatment group versus 120 in the control group). During the entire single-blinded follow-up averaging 15 months, the treatment group had a 37% relative risk reduction in heart failure hospitalizations versus the control group (Fig. 26-7). Most pressure-based medication changes (about 75%) involved, as expected, diuretics and long-acting nitrates. All four prespecified and statistically powered

FIGURE 26-7 Primary (6-month) and extended results of the CHAMPION trial for the primary endpoint of rate of hospitalization for heart failure (HF). RRR = relative risk reduction. (Modified from Abraham WT, Adamson PB, Bourge RC, et al: Wireless pulmonary artery haemodynamic monitoring in chronic heart failure: A randomised controlled trial. *Lancet* 377:658, 2011.)

secondary endpoints were met and favored the treatment group, including reduction in pulmonary artery pressure, proportion of patients hospitalized for heart failure, days alive and out of the hospital for heart failure, and quality-of-life score. The rate of freedom from device-related or system-related complications was 98.6%, and the rate of overall freedom from pressure sensor failures was 100%.

One of these systems, an implantable left atrial pressure monitoring system, may radically change the way that heart failure patients are chronically managed by promoting a physician-directed, patient self-management paradigm for use. Use of this system is similar to how diabetic individuals self-titrate insulin with the aid of a glucometer. Preliminary data have demonstrated the feasibility and potential usefulness of this approach in patients with heart failure.⁴²

SUMMARY AND FUTURE DIRECTIONS

CRT offers a therapeutic approach for treating patients with ventricular dyssynchrony and heart failure. Substantial experience suggests that it is safe and effective, with patients demonstrating significant improvement in both clinical symptoms and multiple measures of functional status, exercise capacity, and outcomes. Recommendations for CRT are now based not only on QRS duration but also on morphology. Prophylactic implantation of an ICD is also of proven benefit in heart failure patients. Implantable monitoring technologies have the potential to improve our ability to avoid episodes of heart failure decompensation and may improve the natural history of the disease.

GUIDELINES

Cardiac Resynchronization Therapy and Implantable Cardioverter-Defibrillators for Heart Failure with a Reduced Ejection Fraction

William T. Abraham

In 2012, the American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) updated the 2008 guidelines for device-based therapy for cardiac rhythm abnormalities.¹ These revised guidelines were incorporated into the 2013 American College of Cardiology Foundation (ACCF)/AHA heart failure guidelines.² The revised guidelines (**Table 26G-1**) include a comprehensive revision of indications for cardiac resynchronization therapy

(CRT) based on all available studies through 2013. The guidelines expanded the indications for CRT to some New York Heart Association (NYHA) class II and very selected class I patients, limit CRT indications by QRS morphology and QRS duration, and attempt to harmonize indications across NYHA classes when possible. The most certain indications are for patients who have a left ventricular ejection fraction (LVEF) of 35% or less, sinus rhythm, left bundle branch block (LBBB) with a QRS duration of 150 milliseconds or less, and NYHA class II, III, or ambulatory IV symptoms while receiving optimal medical treatment.

Patients with a reduced LVEF are at increased risk for ventricular tachyarrhythmias leading to sudden cardiac death. Patients who have had sustained ventricular tachycardia, ventricular fibrillation, unexplained syncope, or cardiac arrest are at highest risk for recurrence. Indications for implantable cardioverter-defibrillator (ICD) therapy as secondary prevention of sudden cardiac death are also discussed in the 2013 ACCF/AHA guidelines for heart failure (**Table 26G-2**),² as well as in the ACCF/AHA/HRS device-based therapy guidelines.³

TABLE 26G-1 ACCF/AHA Guidelines for Cardiac Resynchronization

CLASS	INDICATION	LEVEL OF EVIDENCE
I	CRT is indicated for patients who have an LVEF of $\leq 35\%$, sinus rhythm, LBBB with a QRS duration of ≥ 150 milliseconds, and NYHA class II, III, or ambulatory IV symptoms while receiving GDMT	Level of evidence A for NYHA class III/I, level of evidence B for NYHA class II
IIa	CRT can be useful for patients who have an LVEF of $\leq 35\%$, sinus rhythm, a non-LBBB pattern with a QRS duration of ≥ 150 milliseconds, and NYHA class III/ambulatory class IV symptoms while receiving GDMT	A
	CRT can be useful for patients who have an LVEF of $\leq 35\%$, sinus rhythm, LBBB with a QRS duration of 120 to 149 milliseconds, and NYHA class II, III, or ambulatory IV symptoms while receiving GDMT	B
	CRT can be useful in patients with atrial fibrillation and an LVEF of $\leq 35\%$ while receiving GDMT if (1) the patient requires ventricular pacing or otherwise meets the criteria for CRT and (2) atrioventricular nodal ablation or pharmacologic rate control will allow almost 100% ventricular pacing with CRT	B
	CRT can be useful for patients receiving GDMT who have an LVEF of $\leq 35\%$ and are undergoing placement of a new or replacement device with an anticipated requirement for significant ($>40\%$) ventricular pacing	C
IIb	CRT may be considered for patients who have an LVEF of $\leq 35\%$, sinus rhythm, a non-LBBB pattern with a QRS duration of 120 to 149 milliseconds, and NYHA class III/ambulatory class IV while receiving GDMT	B
	CRT may be considered for patients who have an LVEF of $\leq 35\%$, sinus rhythm, a non-LBBB pattern with a QRS duration of ≥ 150 milliseconds, and NYHA class II symptoms while receiving GDMT	B
	CRT may be considered for patients who have an LVEF of $\leq 30\%$, an ischemic cause of heart failure, sinus rhythm, LBBB with a QRS duration of ≥ 150 milliseconds, and NYHA class I symptoms while receiving GDMT	C
III: No benefit	CRT is not recommended for patients with NYHA class I or II symptoms and a non-LBBB pattern with a QRS duration <150 milliseconds CRT is not indicated for patients whose comorbid conditions and/or frailty limit survival with good functional capacity to <1 year	

GDMT = guideline-directed medical therapy.

TABLE 26G-2 ACCF/AHA Guidelines for Indications for Implantable Cardioverter-Defibrillators

CLASS	INDICATION	LEVEL OF EVIDENCE
I	ICD therapy is recommended for primary prevention of SCD in selected patients with HFrEF for at least 40 days after MI, an LVEF <35%, and NYHA class II or III symptoms while receiving chronic GDMT who are expected to live >1 year	A
I	ICD therapy is recommended for primary prevention of SCD in selected patients with HFrEF for at least 40 days after MI, an LVEF <30%, and NYHA class I symptoms while receiving GDMT who are expected to live >1 year	B
IIa	To prevent sudden death, placement of an ICD is reasonable in patients with asymptomatic ischemic cardiomyopathy who are at least 40 days after MI, have an LVEF of $\leq 30\%$, are receiving appropriate medical therapy, and have reasonable expectation of survival with good functional status for >1 year	B
IIb	ICD therapy to prevent sudden cardiac death in patients with nonischemic cardiomyopathy who are at least 40 days after MI, have an LVEF <35%, have NYHA functional class II or III symptoms while undergoing chronic optimal medical therapy, and have reasonable expectation of survival for >1 year with good functional status	B
	The usefulness of implantation of an ICD is of uncertain benefit in prolonging meaningful survival in patients with a high risk for nonsudden death as predicted by frequent hospitalizations, advanced frailty, or comorbid conditions such as systemic malignancy or severe renal dysfunction	B

GDMT = guideline-directed medical therapy; HFrEF = heart failure with a reduced ejection fraction; MI = myocardial infarction.

OVERVIEW

Patients with heart failure can be divided into those with (1) heart failure with a *reduced* ejection fraction (HFrEF) and (2) heart failure with a *preserved* ejection fraction (HFpEF). All of these patients, regardless of ejection fraction status (EF value), have the clinical syndrome of heart failure. In addition, many features are similar across the EF spectrum, including abnormal left ventricular (LV) filling dynamics, elevated LV diastolic pressure, LV systolic and diastolic dysfunction, neurohormonal activation, impaired exercise tolerance, frequent hospitalization, and reduced survival.¹⁻⁴ Patients with HFpEF have a devastating 5-year mortality rate (approaching 60%), costly morbidity (6-month hospitalization rate of 50%), and debilitating symptoms (maximum myocardial oxygen consumption [MVO₂] averaging 14 mL/g/min).^{5,6} Clear differences also are recognized between HFpEF and HFrEF. Compared with those with a reduced EF, patients with preserved EF are older and more likely to be female; however, HFpEF occurs in both men and women throughout the 5th to the 9th decades of life.⁷ The most common antecedent disease leading to HFpEF is systolic hypertension, which is present in more than 85% of patients, whereas ischemic heart disease is much less common than in HFrEF.⁷ Differences in cardiovascular structure and function between HFpEF and HFrEF also are well recognized.^{4,8-12} Patients with HFpEF have normal LV end-diastolic volume and normal (or near-normal) EF and stroke volume and commonly exhibit concentric remodeling of either LV chamber and/or cardiomyocytes. Finally, differences also are evident in the effects of pharmacologic treatment in patients with HFrEF versus HFpEF. Standard heart failure therapy shown to be effective in HFrEF has not been found to reduce morbidity or mortality associated with HFpEF, leaving a substantial area of unmet need.¹³

This chapter summarizes the current understanding of the clinical, prognostic, pathophysiologic, and therapeutic information about patients with HFpEF and suggests where future advances are likely to occur.

TERMINOLOGY

A variety of terms have been used to describe patients with what is now called *heart failure with a preserved ejection fraction* (HFpEF). These terms include heart failure with a normal EF, heart failure with

normal systolic function, diastolic heart failure, and diastolic dysfunction heart failure. Heart failure guidelines, recent publications and this chapter use the term HFpEF. The mean EF in normal populations depends somewhat on the method used to measure it but generally is agreed to be above 60%. The lower 95% confidence limit for EF is approximately 55%, whereas an EF greater than 50% often is used as a diagnostic criterion for HFpEF; this term also has been applied to heart failure in some patients with EFs outside the normal range. For example, some randomized controlled trials (RCTs) have included patients with EFs greater than 35%, 40%, or 45%. Therefore, because the term HFpEF has been applied to this broader spectrum of patients with heart failure, the term “heart failure with a normal EF” is less commonly used. Although it is clear that patients with an EF below 50% have abnormalities in systolic function, recent studies have shown that even patients with an EF above 50% may have midwall and/or longitudinal systolic dysfunction. Therefore the term “heart failure with normal systolic function” is not an accurate description even for patients with heart failure and EF above 50%.

Because patients with the clinical syndrome of HFpEF have abnormalities in LV diastolic function, systolic function, and vascular properties; the terms “diastolic heart failure” and “diastolic dysfunction heart failure,” which single out the abnormalities in diastole, are now used less commonly. The term *diastolic dysfunction* refers to abnormalities in LV filling secondary to altered compliance, relaxation, and/or recoil. Abnormalities in diastolic function can occur in the presence or absence of a clinical syndrome of heart failure and with normal or abnormal systolic function. Whereas *diastolic dysfunction* describes abnormal LV performance, *HFpEF* describes a clinical syndrome of heart failure.

EPIDEMIOLOGY

A substantial proportion (more than 50% in many studies) of patients who are diagnosed or hospitalized with heart failure have HFpEF.^{14,15} This observation is consistent among different racial groups, geographic regions, and hospital- and community-based studies. The prevalence of HFpEF increases dramatically with age, and this heart failure syndrome is much more common in women than in men at any age (Fig. 27-1). The prevalence of HFpEF appears to be increasing, perhaps as a function of the aging population and increased recognition of the clinical entity. The distribution of EF across

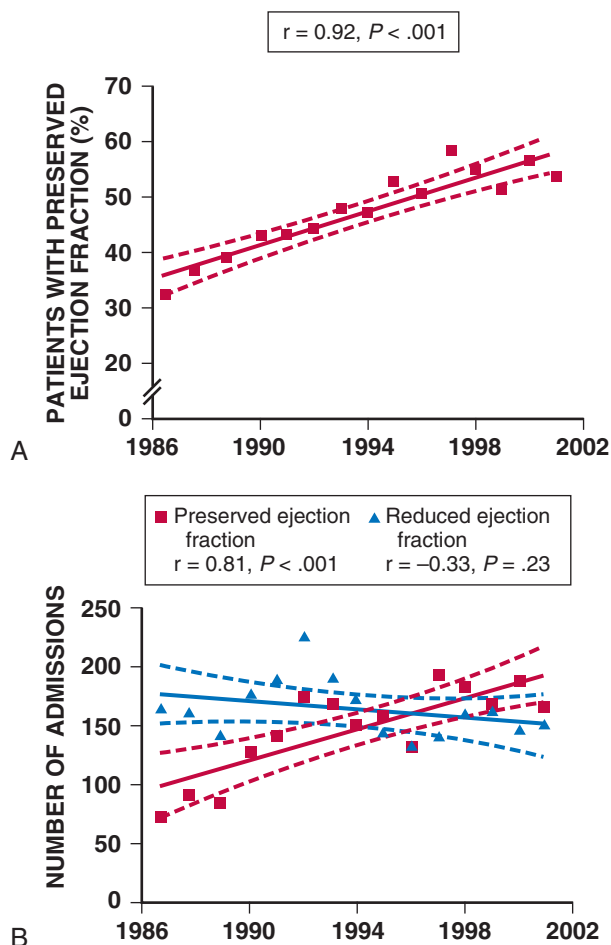

FIGURE 27-1 Prevalence and heart failure–related hospital admissions in patients with HFpEF. **A**, The percentage of patients with the HFpEF form of heart failure increased from 1987 to 2001, demonstrating that HFpEF prevalence continues to rise. **B**, Over this same 15-year time frame, the number of heart failure–related hospitalizations in patients with HFrEF remained stable or trended slightly downward, whereas in patients with HFpEF, the number increased significantly. CHF = congestive heart failure. (From Owan TE, Hodge DO, Herges RM, et al: Trends in prevalence and outcomes of heart failure with preserved ejection fraction. *N Engl J Med* 355:251, 2006.)

FIGURE 27-2 Distribution of left ventricular EF (LVEF) in patients hospitalized with a primary discharge diagnosis of heart failure. Data from the OPTIMIZE-HF (Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure) registry examined EF in 48,612 subjects and demonstrated a bimodal distribution, with peaks centered on 35% and 55%. (From Fonarow GC, Stough WG, Abraham WT, et al: Characteristics, treatments, and outcomes of patients with preserved systolic function hospitalized for heart failure: a report from the OPTIMIZE-HF Registry. *J Am Coll Cardiol* 50:7687, 2007.)

unselected populations of patients with heart failure is bimodal, with peaks centered on 35% and 55%¹⁶ (Fig. 27-2). These data further emphasize that HFpEF is an important cause of the heart failure syndrome.

NATURAL HISTORY

Mortality

The 5-year survival rate for all patients with heart failure, regardless of EF, is less than 50%. Although survival has improved over time for patients with HFrEF, it has not changed for patients with HFpEF (Fig. 27-3A, B).¹⁴ Some epidemiologic studies have found that all-cause mortality for HFpEF is similar to that for HFrEF; other epidemiologic studies and RCTs suggest that all-cause mortality is somewhat lower in HFpEF than in HFrEF (see Chapter 25). For example, three RCTs have enrolled both patients with HFpEF and those with HFrEF, allowed direct comparisons, and demonstrated a lower mortality rate in HFpEF versus HFrEF.¹⁷ Taken together, data from epidemiologic studies of HFpEF find that the annual mortality is approximately 10%, but RCTs in patients with HFpEF suggest that the annual mortality is about 5%. This apparent difference may be due to the exclusion of patients with the comorbid conditions from the RCTs. However, the mortality rates found in patients with HFpEF are not solely due to the comorbid diseases. In the RCTs, patients with HFpEF, who have antecedent and comorbid factors such as hypertension, coronary artery disease, and diabetes mellitus, were found to have more than twice the mortality rate of patients with hypertension, coronary artery disease, or diabetes who do not have HFpEF¹⁷ (Fig. 27-3C, D).

Mode of Death

Most (>70%) of the deaths in patients with HFpEF are cardiovascular in nature, with 20% due to heart failure and 35% due to sudden death¹⁸ (Table 27-1). This distribution of modes of cardiovascular death is similar to that for HFrEF. The incidence of noncardiovascular deaths is significantly higher for HFpEF (30%) than for HFrEF (15%), reflecting the higher age and increased comorbidity in patients with HFpEF.

Morbidity

Among patients with HFpEF, morbidity rates are comparable to those with HFrEF; heart failure–related hospital readmission rates

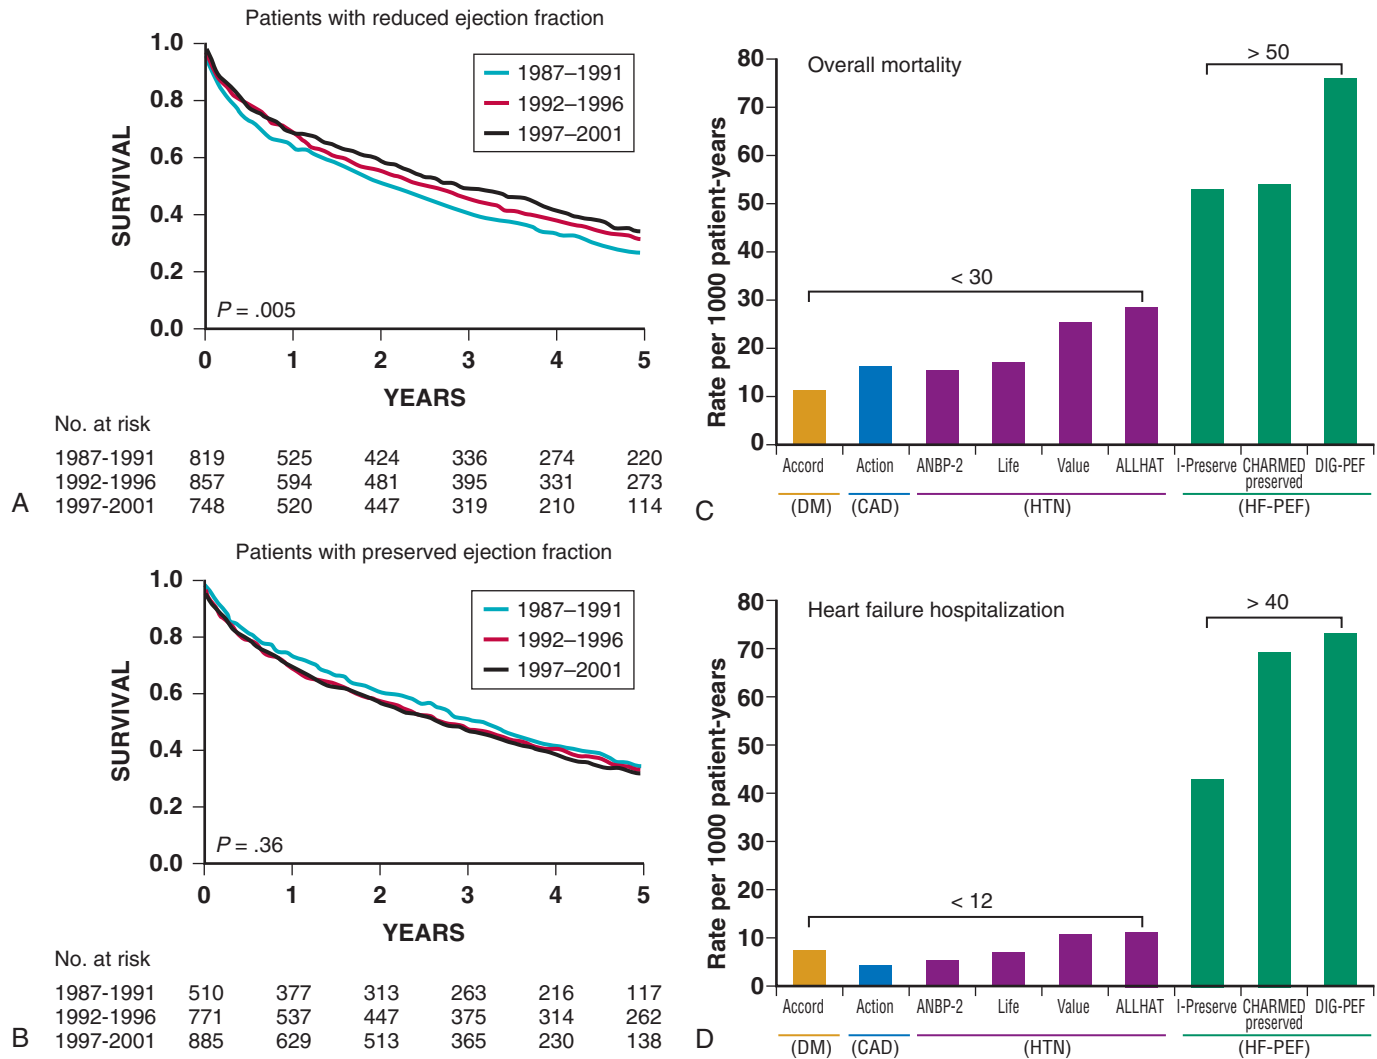

FIGURE 27-3 Mortality and morbidity in patients with HFrEF or HFpEF in epidemiologic studies versus RCTs. **A, B**, In epidemiologic studies, 5-year survival rate for all patients with heart failure, regardless of EF, is less than 50%; survival has improved over time in HFrEF but has not changed in HFpEF. RCTs suggest that mortality is somewhat lower in HFpEF than in HFrEF. **C, D**, Mortality and morbidity in patients with HFpEF do not arise solely from the comorbid conditions. In the RCTs, among patients with HFpEF, who have antecedent and comorbid factors such as hypertension (HTN), coronary artery disease (CAD), and diabetes mellitus (DM), mortality rate and heart failure–related hospitalization rate are more than twice those in patients with HTN, CAD, or DM who do not have congestive heart failure. (**A, B**, From Owan TE, Hodge DO, Herges RM, et al: Trends in prevalence and outcomes of heart failure with preserved ejection fraction. *N Engl J Med* 355:251, 2006. **C, D**, From Campbell R, Jhund PS, Castagno D, et al: What have we learnt about patients with heart failure and preserved ejection fraction (HF-PEF) from DIG-PEF, CHARM-preserved, and I-Preserve? *J Am Coll Cardiol* 60:2349, 2012.)

TABLE 27-1 Mode of Death Distribution in Randomized Controlled Trials

CATEGORY	HFPEF N (%)				HFREF MEAN % (RANGE)

From Zile MR, Gaasch WH, Anand IS, et al: Mode of death in patients with heart failure and a preserved ejection fraction: Results from the Irbesartan in Heart Failure with Preserved Ejection Fraction Study (I-Preserve) trial. *Circulation* 121:1393-2010.

approximate 50% at 6 months for both HFrEF and HFpEF. The lifetime burden for all-cause hospitalization is high and nearly equivalent for patients with HFpEF and those with HFrEF. All patients with heart failure (both HFpEF and HFrEF) have many comorbid conditions that influence both morbidity and mortality.¹⁹ Like mortality, the heart failure hospitalization rates in patients with HFpEF are not based solely on the presence of antecedent or comorbid conditions themselves. Data from RCTs have shown that the heart failure hospitalization rates in patients with HFpEF (who have antecedent and comorbid factors such as hypertension, coronary artery disease, and diabetes mellitus) are more than twice than those in patients with hypertension, coronary artery disease, or diabetes mellitus who do not have HFpEF (see Fig. 27-3D).¹⁷ Rates of progressive functional decline after hospital admission for heart failure also are similar in patients with HFpEF and in those with HFrEF. In addition to heart failure–related hospitalizations, abnormalities in exercise tolerance, MVO₂, and quality-of-life assessment are similar for HFrEF and HFpEF.

Conversion from Heart Failure with Preserved Ejection Fraction to Heart Failure with Reduced Ejection Fraction

Conversion from HFpEF to HFrEF is uncommon and generally is associated with an incident injury (such as myocardial ischemia).^{1,20-22} For example, in one study, 1233 patients with heart failure had serial echocardiograms to determine the time course of changes in the LV EF over a 5-year observation period.²¹ On average, the LV EF decreased by approximately 0.06 over 5 years in the HFpEF group, whereas it increased by nearly 0.07 in the HFrEF group. These rates should be interpreted in light of the following limitations: HFpEF and HFrEF were divided on the basis of an EF of 50%. This value is an arbitrary cut-off. Clearly, patients with EFs of 51% and those with EFs of 49% are not substantially different and are likely to cross back and forth across the threshold. In addition, no uniform deterioration in EF occurred in patients with HFpEF. Some experienced no fall in EF, and a majority (>60%) did not demonstrate a decline in EF below 50%. Another prospective study of 343 subjects with concentric LV remodeling (but no heart failure) found that over 7 years, only 7% developed eccentric remodeling with LV dilation and a fall in EF.²² Thus, although treatment of HFrEF may result in normalization of EF, a decline in EF in HFpEF appears usually to be due to an intercurrent event, most frequently ischemic injury.

PATHOPHYSIOLOGY

The pathophysiologic mechanisms that cause the development of HFpEF are reflected in changes in LV relaxation and filling, LV structural remodeling and altered geometry, and changes in LV and vascular compliance (Table 27-2).

Normal Diastolic Properties

Normal diastolic function (see Chapter 21) allows the ventricle to fill adequately during rest and exercise, without an abnormal increase in left atrial (LA) pressure. The phases of diastole are *isovolumic pressure decline* and *filling*. The filling phase is divided into early rapid filling, diastasis, and atrial systole. *Early rapid filling* contributes 70% to 80% of LV filling in normal individuals. This contribution diminishes with age and various disease states. Early diastolic filling is driven by the LA-to-LV pressure gradient, which is dependent on a complex interplay of factors—myocardial relaxation, LV elastic recoil, LV diastolic stiffness, LA pressures, ventricular interaction, pericardial constraint, pulmonary vein properties, and mitral orifice area. *Diastasis* occurs in mid-diastole, when the LA and LV pressures usually are almost equal. It contributes less than 5% of the LV filling, and its duration shortens with tachycardia. In normal subjects, *atrial systole* contributes 15% to 25% of LV diastolic filling without raising the mean LA pressure. This contribution depends on the PR interval, atrial inotropic state, atrial preload, atrial afterload, autonomic tone, and heart rate.

Left Ventricular Relaxation

LV relaxation is an active, energy-dependent process that begins with the decay of force-generating capacity, follows the completion of the

TABLE 27-2 Mechanisms/Factors Contributing to the Pathophysiology of Heart Failure with Preserved Ejection Fraction

Cardiovascular
LV Structure
Concentric remodeling, LV hypertrophy
LV Function
Diastolic dysfunction: abnormal relaxation, decreased recoil, abnormal filling, decreased distensibility, increased diastolic pressure
Systolic dysfunction: abnormal midwall and long-axis shortening, decreased twist
Hemodynamic load
Increased afterload and filling load
Heterogeneity
Dyssynergy, dyssynchrony
Left atrial structure and function
Increased LA volume and stiffness, decreased LA reservoir function, passive conduit function and active booster pump function
Ischemia
Subendocardial and microvascular disease, impaired coronary, pulmonary and peripheral flow reserve
Rate and rhythm abnormalities
Chronotropic incompetence, atrial fibrillation, supraventricular tachycardia
Vascular dysfunction
Arterial stiffening, endothelial dysfunction
Cardiomyocyte
Abnormal calcium homeostasis (↑ diastolic calcium or ↓ rate of calcium reuptake → incomplete or impaired relaxation)
Sarcolemmal calcium channels (Na ⁺ /Ca ²⁺ exchanger and calcium pump)
Sarcoplasmic reticulum Ca ²⁺ ATPase (SERCA) abundance and function
Proteins modifying SERCA activity: phospholamban, calmodulin, calsequestrin abundance and phosphorylation state
Sarcoplasmic reticulum calcium release channels
Energetics (↓ ATP or ↑ ADP slows actin-myosin cross-bridge release)
ADP/ATP ratio, ADP and P _i concentration, phosphocreatine shuttle function
Proteins regulating cross-bridge formation and calcium sensitivity
Troponin C: calcium binding
Troponin I: phosphorylation state
Cytoskeletal proteins
Microtubules (increased density) → ↑ diastolic stiffness
Titin isoforms (↑ noncompliant isoform and phosphorylation state) → ↑ diastolic stiffness
Extracellular Matrix
Collagen structure, geometry, content, collagen I/III ratio
Collagen homeostasis, synthesis, postsynthetic processing, posttranslational cross-linking, degradation
Basement membrane proteins
Bioactive proteins and peptides: MMP/TIMP, SPARC, TGF-β
Fibroblast structure, function, phenotype
Myofibroblast transdifferentiation
ExtraCardiac
Extrinsic forces (RV-LV interaction and pericardial constraint)
Peripheral muscle and ergoreflex dysfunction
Pulmonary hypertension (secondary to chronic pulmonary venous hypertension)
Neurohormonal activation
Comorbid conditions (renal dysfunction, anemia, chronic lung disease)

SPARC = secreted protein, acidic and rich in cysteine [osteonectin].

ejection phase of systole, and continues through isovolumic pressure decline and the rapid filling phase. Filling is dependent both on active relaxation and on the recoil/suction that results from the release of potential energy stored during systole by contraction. Thus blood is effectively “pulled” into the left ventricle.²³ In normal hearts, over a range of normal heart rates, relaxation and recoil are adequate

to allow LA pressures to remain normal. In addition, catecholamine-induced enhancement of relaxation and recoil during exercise lowers LV pressures in early diastole, thereby increasing the LA-to-LV pressure gradient without increasing LA pressures as well as enhancing filling during exercise. By contrast, in patients with HFpEF, relaxation and recoil are abnormal at rest and are not enhanced during increased HR or exercise. As a result, filling can be maintained only by increased LA pressure; blood must be “pushed” into the left ventricle.

Isovolumic Pressure Decline. The time course of isovolumetric pressure decline has been quantitatively described by the peak rate of pressure fall (dP/dt_{min}) and the time constant τ (tau) of the exponential fall in LV isovolumetric pressure. Each of these requires that LV pressure be measured using a micromanometer-tipped catheter.

dP/dt_{min} measures the rate of pressure decline at a single point in time, is strongly influenced by the LV pressure at the time of aortic valve closure, and therefore, like all indices of diastolic function, is afterload-dependent. Patients with HFpEF have a larger dP/dt_{min} , signifying that relaxation rate is decreased.

The time constant τ describes the rate of LV pressure decline throughout isovolumic relaxation. Pressure (P) and time (t) data during the period from end-systole (aortic valve closure) to the onset of LV filling (mitral valve opening) are fit to an exponential equation such as the following: $LV\ pressure = P_0 e^{-t/\tau}$, where P_0 is LV pressure at end-ejection and τ is the exponential time constant. The larger the value of τ , the longer it takes for the LV pressure to fall and the more impaired is relaxation. A normal value for τ is less than 40 milliseconds in most age groups, suggesting that relaxation is nearly complete by $3.5 \times \tau$ (less than 140 milliseconds).

The isovolumic relaxation time (IVRT) also can be estimated by echo techniques as the time between aortic valve closure and mitral valve opening. Although less precise than τ , IVRT is useful in the noninvasive assessment of diastolic properties. However, IVRT depends not only on the rate of LV relaxation but also on the aortic pressure at the time of aortic valve closure and the LA pressure at mitral valve opening. Thus IVRT can be increased by an elevation of aortic pressure or decreased by an increase in LA pressure. The time course of LV pressure decline during isovolumetric relaxation can also be characterized using noninvasive Doppler measurement of the velocity of a regurgitant jet across the mitral valve. In this method, the modified Bernoulli equation is used to approximate LV pressure during isovolumetric relaxation, allowing calculation of the maximum rate of LV pressure decline and the exponential time constant.

Recoil and Left Ventricular Filling. During systole, potential energy is stored in the elastic elements of the cardiomyocytes and extracellular matrix (ECM).²³ The elastic elements are compressed and twisted during systolic contraction. During relaxation, this potential energy is released as the elastic elements recoil and return to their original length and orientation. Recoil causes LV pressure to fall rapidly during isovolumetric relaxation. Furthermore, for the first 30 to 40 milliseconds after mitral valve opening, the relaxation of LV wall tension normally is rapid enough to cause LV pressure to continue to decline despite an increase in LV volume. This fall in LV pressure produces an early diastolic pressure gradient from the LA that extends to the LV apex (see [Fig. e27-1A](#)). This accelerates blood out of the LA and produces rapid early diastolic flow that quickly propagates to the apex. Because the diastolic intraventricular pressure gradient pulls blood to the apex, it can be considered a measure of LV suction. It is reduced in both experimental models and in patients with ischemia, hypertrophic cardiomyopathy,²⁴ and heart failure including HFpEF.²⁵⁻²⁷ The intraventricular pressure gradient can be measured noninvasively from the diastolic spatial-temporal velocity map obtained using apical color M-mode echocardiography.

Because the LV apex remains fixed during the cardiac cycle, the mitral annular velocity provides a measure of long-axis lengthening rate.²⁸ Under normal conditions, peak early diastolic mitral annular velocity (e') occurs coincidentally with or before the mitral E (see [Fig. e27-1A, B](#)).^{29,30} This is a manifestation of the symmetric expansion of the left ventricle in early diastole as blood moves rapidly to the LV apex in response to a progressive pressure gradient from the left atrium to the LV apex. In addition, the rapid recoil of the mitral annulus and valve into the left atrium early in diastole relocates blood from the left atrium into the left ventricle. Under normal circumstances, both E and e' respond to changes in the LA-to-LV pressure gradient. For example, both E and e' normally increase in response to increased volume load and exercise.³⁰⁻³²

Determinants of Left Ventricular Relaxation

LV relaxation is under the control of multiple factors that include hemodynamic load (early diastolic load and afterload), myofiber inactivation (see discussion of cellular determinants further on), and the uniformity of the distribution of load and inactivation in space and time (dyssynchrony, dyssynergy, Treppe). Each of these determinants may affect indices of diastolic relaxation, recoil and filling.

Hemodynamic Load

Both isovolumic pressure decline and early filling are affected by afterload (LV systolic stress). An increase in LV systolic stress results in a delay in and slowed rate of pressure decline and early filling. Increases in systolic load may have different effects, depending on when the load is imposed during systole. Increases in LV pressure late in systole hasten the onset of LV relaxation, but relaxation occurs at a slower rate (increased τ). Increases in LV pressure late in systole occur with aging because of age-related vascular stiffening, which alters the timing of reflected pressure wave in the vascular tree so that the reflected wave arrives in late systole rather than diastole. In clinical practice, an acute increase in blood pressure either at rest or during exercise will impair ejection, slow pressure decline, prolong time to complete relaxation, and reduce recoil. These changes in relaxation decrease the LA-to-LV gradient, decrease early filling, and result in increased LV diastolic and LA pressure. In addition, the load present at the time of mitral valve opening (LA-to-LV gradient, i.e., early diastolic load) affects early LV filling.

Heterogeneity

Synchrony (timing of relaxation of the different myocardial segments) and *synergy* (extent to which myocardial segments relax) will enhance LV relaxation, whereas *dyssynchrony* or *dyssynergy* (e.g., caused by infarction, ischemia, asymmetry of hypertrophy, or conduction abnormalities) will impair global LV relaxation. Dyssynchrony, measured using a variety of echocardiographic measurements, may be present in patients with HFpEF, particularly those with left bundle branch block (LBBB) or right ventricular (RV) pacing. Whether or not treatment aimed at resynchronization (i.e., cardiac resynchronization therapy [CRT]) will effect clinical improvement in patients with HFpEF is currently under investigation.

Cellular Mechanisms

Myofiber inactivation refers to the many cellular processes ([Chapter 21](#)) that ultimately influence the process by which the left ventricle, its constitutive cardiomyocytes and individual sarcomeres return to a normal end-diastolic length with minimum cross-bridge cycling and low force generation. To accomplish this state of complete relaxation requires (1) calcium resequestration into the sarcoplasmic reticulum, followed by calcium extrusion into the extracellular space; (2) availability of sufficient ATP; (3) normal myofilament function; and (4) normal elastic properties of the cardiomyocyte and the ECM.

Additional material on this topic is presented in an online supplement for this chapter (Cellular Mechanisms of Myocardial Relaxation).

Prevalence and Prognosis for Abnormal Relaxation

Impaired relaxation is present in HFpEF and contributes to the development of elevated LA pressure at rest. The rate of relaxation is further impaired during exercise and hemodynamic stress. Any factor that shortens the diastolic filling period (prolonged contraction or long PR interval) will enhance the effect of impaired relaxation on LV diastolic pressures during filling and thus affect the mean LA pressure needed to fill the left ventricle. Whether therapies to enhance relaxation directly and specifically can be developed, and whether such therapies will relieve symptoms, remains an area of active investigation.

Left Ventricular Diastolic Stiffness, Compliance, and Distensibility

Methods of Measurement

The passive characteristics of the left ventricle during diastole can be described by the passive diastolic pressure-volume relationship

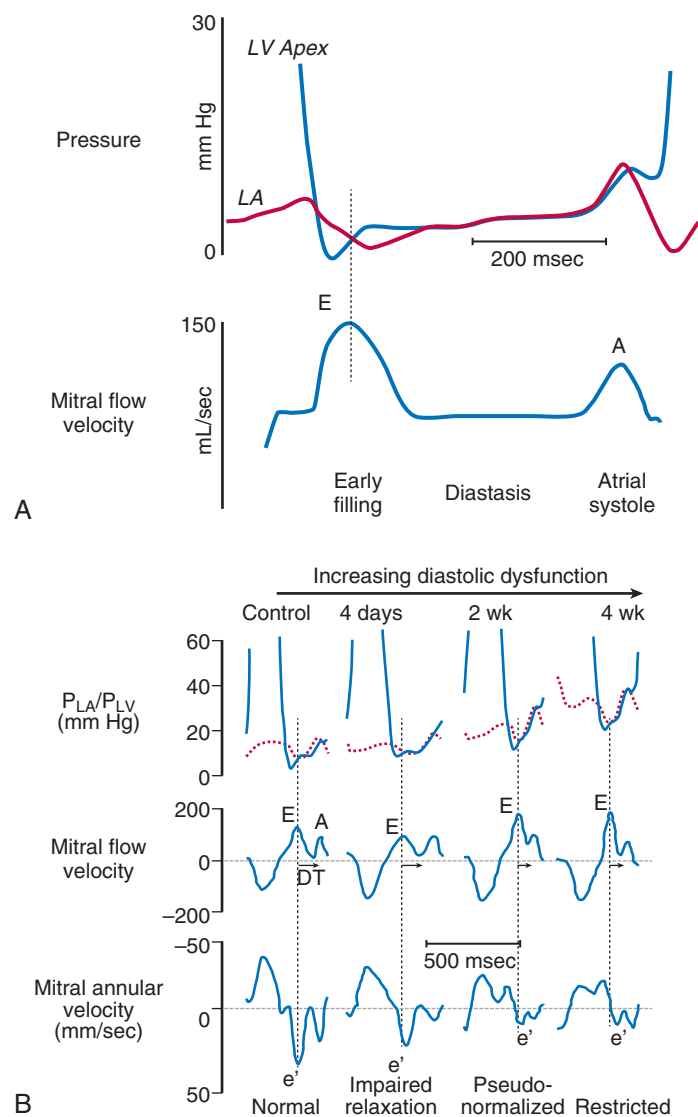

FIGURE e27-1 **A**, LV filling dynamics recorded in a conscious animal. **B**, Recordings in a conscious animal of pressures in the apex of the left ventricle (P_{LV}) and left atrium (P_{LA}) and the mitral valve flow velocity. The late diastolic mitral flow velocity (A), peak early diastolic flow velocity (E), peak early mitral annular velocity (e'), and E deceleration time (DT) are shown. (A and B, From Little WC, Oh JK: Echocardiographic evaluation of diastolic function can be used to guide clinical care. *Circulation* 120:802, 2009.)

Cellular Mechanisms of Myocardial Relaxation

The detachment of actin from myosin requires prompt decreases in cytosolic calcium concentrations during diastole. Several causes for prolongation of the calcium transient are recognized (see Chapter 21), but particularly reduced reuptake of calcium into the sarcoplasmic reticulum secondary to decreases in the amount or activity of the sarcoplasmic reticulum calcium-ATPase (SERCA).¹ Beta-adrenergic stimulation activates protein kinase A (PKA), which phosphorylates phospholamban and removes its tonic inhibition of SERCA activity, thereby hastening calcium reuptake and LV relaxation. Beta-adrenergic/PKA-mediated phosphorylation of troponin I also hastens relaxation by decreasing calcium sensitivity, and reduced troponin I phosphorylation may accentuate afterload-induced changes in relaxation.² Impaired beta-adrenergic signaling is well established in HFrEF (Chapter 22), in animal models of pressure overload with relevance to HFpEF, and as indicated by increasing clinical evidence,

in patients with HFpEF.³ Chronic catecholamine activation contributes to beta-adrenergic receptor downregulation and desensitization, and catecholamine levels are elevated in HFpEF, suggesting that impaired beta-adrenergic signaling may contribute to relaxation impairment in HFpEF. More recently, chronotropic incompetence and impaired systolic and lusitropic reserve function have been reported in heart failure with a normal EF (HFnEF), findings that further support a role for impaired beta-adrenergic signaling in HFpEF.⁴⁻⁹ Phospholamban phosphorylation also may be reduced by increases in protein kinase C (PKC) through effects on protein phosphatases.¹⁰ Protein kinase C (PKC) activity is increased in HFrEF and in animal models of pressure overload with relevance to HFpEF. Therefore impaired beta-adrenergic/PKA signaling, reduced SERCA amount and activity, increased PKC activity, and decreased Na^+/Ca^{2+} exchanger function all contribute to the development of abnormal diastolic function and may provide potential novel therapeutic targets for HFpEF therapies.

Energy (ATP) supply influences relaxation by regulating calcium reuptake by way of SERCA and by influencing cross-bridge detachment at the myosin heads, where the phosphocreatine shuttle mechanism ensures delivery of ATP from the mitochondria and removal of ADP and inorganic phosphate (P_i) from the site of cross-bridge formation (see Chapter 22). Inadequate ATP and increased levels of ADP at the cross-bridge sites impair cross-bridge detachment and slow relaxation. Impaired relaxation is the first functional abnormality to arise during acute ischemia and with persistent ischemia is accompanied by parallel upward shifts of the diastolic pressure-volume relationship (decreased distensibility) due to rigor bonds. Both features may contribute to the elevated filling pressures with ischemia. Hypertrophied hearts are more sensitive to ischemia, with greater increases in filling pressures resulting from ischemia. Impaired creatine kinase ATP kinetics have been described in patients with HFpEF and linked to impaired relaxation and systolic reserve function.⁷

Changes in myofilament proteins (such as titin) and extramyofibrillar proteins (such as microtubules) also may affect the elastic properties of the cardiomyocyte and alter diastolic function in patients with HFpEF. Changes in titin isoforms and phosphorylation state affect cardiomyocyte distensibility. Microtubule polymerization state affects cardiomyocyte distensibility. These proteins, along with calcium homeostasis, myofilament function, and energetics, determine the elastic properties of the cardiomyocyte (and, as a result, the left ventricle) and determine the distending force necessary to achieve an adequate end-diastolic volume and resultant systolic volume.

(DPVR).²³ Optimally, this relationship should be constructed from points that are obtained after relaxation is complete and at slow filling rates, so that viscous effects are not present. In practice, this can be approximated using points obtained late in diastole, when relaxation is assumed to be complete, by correcting pressure data affected by incomplete relaxation or by using data from variably loaded beats at end-diastole. The resultant DPVR is nonlinear and can be approximated by an exponential function. LV stiffness is defined as the ratio of LV diastolic pressure and LV diastolic volume (LV dP/dV) at any given LV diastolic volume. LV compliance is the reciprocal of stiffness (LV dV/dP). Because the DPVR can be approximated as an exponential, stiffness will increase as the left ventricle fills to higher LV diastolic volumes; thus as the left ventricle fills, it becomes stiffer. LV diastolic distensibility is defined as the end-diastolic pressure required to distend the left ventricle to an end-diastolic volume. Patients with HFpEF have reduced distensibility, indicated by a normal or reduced end-diastolic volume and an elevated end-diastolic pressure.^{2,33} Because the DPVR can be approximated by an exponential function, its position and shape can be described by the constants within an equation such as the following: $P = \alpha \times e^{\beta V}$, where α and β represent the “stiffness constants.” It should be recognized that β does not indicate stiffness but instead describes how rapidly stiffness increased with increases in volume ($\beta = [dP/dV]/V$). The “stiffness constants” derived in this fashion can be used to compare passive diastolic properties in different patients or patient groups. The end-diastolic pressure-versus-volume ratio (instantaneous operative distensibility) also can be used in comparing patients or patient groups. Patients with HFpEF have abnormal DPVRs with elevated β and abnormal distensibility (Fig. 27-4).

Patients with heart failure and an increased LV diastolic pressure can be divided into four groups defined by patterns of DPVR, as depicted in Figure 27-5. DPVR in patients with HFpEF typically is characterized by the graphed curve D in the figure, in which eccentric remodeling results in a shift of the DPVR to the right, representing an increase in distensibility. It should be recognized that although the ventricle is more distensible, the LV end-diastolic volume in these patients typically is very large and the end-diastolic stiffness in the operating region is high. DPVR in patients with HFpEF may be characterized by graphed curves A to C. In Figure 27-5C, pericardial

FIGURE 27-4 Difference in diastolic chamber distensibility in patients with HFpEF (in red) versus HFrEF (in black) versus age- and gender-matched referent control subjects (in green). Compared with that in the control subjects, the diastolic pressure-volume relationship in patients with HFpEF is shifted upward and to the left, such that for any given LV volume, pressure is higher in HFpEF, indicating decreased distensibility (increased stiffness). By contrast, in patients with HFrEF, the diastolic pressure-volume relationship is shifted to the right, indicating increased distensibility. (From Zile MR, Baicu CF, Gaasch WH: Diastolic heart failure—abnormalities in active relaxation and passive stiffness of the left ventricle. *N Engl J Med* 350:1953, 2004; and Aurigemma GP, Zile MR, Gaasch WH: Contractile behavior in the left ventricle in diastolic heart failure: With emphasis on regional systolic function. *Circulation* 113:296, 2006.)

constraint causes a parallel upward shift in the DPVR. In patients with HFpEF, when relaxation is markedly prolonged and diastole is abbreviated (as seen in Fig. 27-5A), LV diastolic pressure falls throughout diastole but remains increased. In the most prevalent pattern in HFpEF (depicted in Fig. 27-5B), the DPVR is shifted upward and to the left, indicating reduced distensibility, where LV pressure is increased at any LV volume.

Determinants of Left Ventricular Pressure-versus-Volume Relationship

Two of the determinants associated with an upward and leftward shift of the DPVR in patients with HFpEF are the presence of LV and cardiomyocyte concentric remodeling and hypertrophy and changes in the material properties of myocardial muscle itself (i.e., myocardial stiffness). Myocardial diastolic stiffness can be determined by assessing the myocardial diastolic LV stress versus strain relationship. The stress-strain relationship represents the resistance of the myocardium to stretch (increase in length) when subjected to stress (distending force). Calculation of stress requires the use of a geometric model of the LV, and the calculation of strain requires assumption of the unstressed LV volume, which cannot be directly measured in the intact circulation. In addition to these potential theoretical limitations, these calculations require accurate measurements over a wide range of LV pressures, volumes, dimensions, and wall thicknesses. These challenges in determining myocardial stress-strain relationships have limited their clinical application, but they remain important to basic and translational research efforts.

LV DPVR is affected by factors that influence the cardiac ECM such as fibrillar collagen, cellular structure and processes at the cardiomyocyte level such as calcium homeostasis and energetics (discussed previously), and myofilament and cytoskeletal proteins such as titin and microtubules.³⁴⁻³⁶

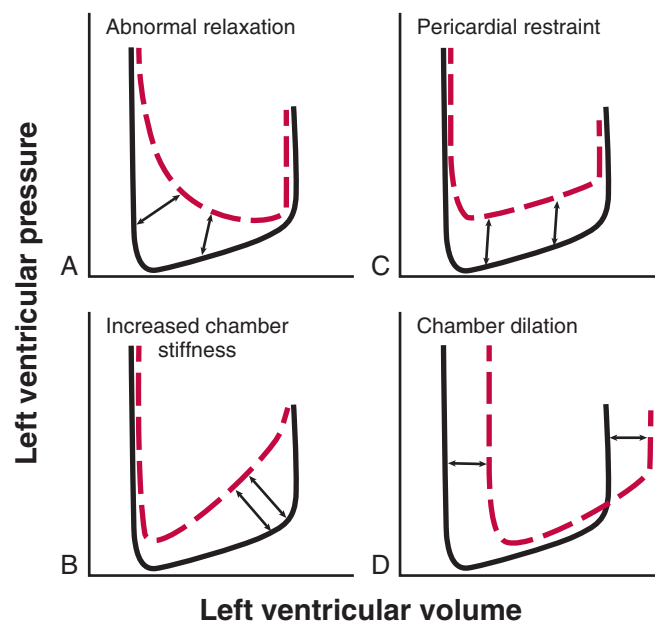

FIGURE 27-5 Mechanisms that result in increased LV diastolic pressure. Among patients with heart failure and an increased LV diastolic pressure, four patterns of DPVR can be discerned. DPVR in patients with HFpEF may be characterized by graphed curves A to C. In the most prevalent pattern in HFpEF, represented by curve B, the DPVR is shifted upward and to the left, indicating reduced distensibility, where LV pressure is increased at any LV volume. In patients with HFpEF, when relaxation is markedly prolonged and diastole is abbreviated, as shown in curve A, LV diastolic pressure falls throughout diastole but remains increased. In curve C, pericardial constraint causes a parallel upward shift in the DPVR. DPVR in patients with HFrEF typically is characterized by curve D, in which eccentric remodeling results in a shift of the DPVR to the right, representing an increase in distensibility. It should be recognized that although the ventricle is more distensible, the end-diastolic volume in these patients typically is very large and the end-diastolic stiffness in the operating region is high. (From Carroll JD, Lang RM, Neumann AL, et al: The differential effects of positive inotropic and vasodilator therapy on diastolic properties in patients with congestive cardiomyopathy. *Circulation* 74:815, 1986.)

Extracellular Matrix

The ECM consists of fibrillar proteins including collagen type I and type III, elastin, and proteoglycans; basement membrane proteins such as collagen type IV, laminin, and fibronectin; and a large number of bioactive peptides and proteins such as matrix metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs), signaling proteins such as transforming growth factor- β (TGF- β), and cytokines (see also Chapter 22). The myocardial collagen network is composed of endomysial fibers surrounding individual myocytes and capillaries; perimysial fibers, which interweave muscle bundles; and epimysial fibers, which form a matrix adjacent to the epicardial and endocardial surfaces. ECM structure is dynamic and regulated by physical, neurohormonal, and inflammatory mediators. These modulate the four steps in collagen homeostasis: collagen synthesis, post-synthetic processing, posttranslational cross-linking, and degradation (see Chapter 22).³⁷⁻⁴⁰ The ECM fibrillar collagen content is increased in patients with HFpEF (Fig. 27-6). Experimental studies have shown that acute degradation of collagen fibers by collagenase perfusion or activation of MMPs results in decreased LV stiffness. Animal models have demonstrated that interventions associated with increases or decreases in myocardial fibrosis are associated with increased or decreased LV diastolic stiffness. Thus evidence that the ECM can contribute to diastolic dysfunction by increasing diastolic stiffness or contributing to impairment in relaxation by altering regional loading or uniformity is strong and supports the potential therapeutic strategy of preventing or reducing fibrosis in the therapy of HFpEF.

Myofilament and Extramyofilament Proteins

The giant myocardial protein titin spans the Z-lines and serves as a molecular spring that resists distension, thereby contributing to LV stiffness (Chapter 21). A number of factors, including titin isoform switches (to a less compliant N2B isoform) and titin phosphorylation state, affect diastolic stiffness. Such alterations in titin are present in HFpEF contributing to increased LV diastolic stiffness.^{41,42} Interaction of titin with other signaling molecules and with ion channels also

may contribute to diastolic stiffness. The role of alterations in titin and the interactions of titin with the ECM in patients with HFpEF constitute an important area of investigation. In addition to titin, other cardiomyocyte structural proteins and changes in their phosphorylation state may affect diastolic stiffness. These include changes in myosin-binding proteins, microtubules, and others.

Prevalence and Prognosis for Decreased Diastolic Distensibility

Measuring the DPVR in large series of patients with HFpEF, particularly in RCTs, is impractical. However, several studies using both invasive measurements and noninvasive estimates of LV stiffness have shown that LV diastolic stiffness is increased in patients with HFpEF as compared with both age-matched control cohorts and patients with hypertensive LV hypertrophy but without heart failure.^{2,33,43,44} The exact prevalence in either epidemiologic or pathophysiologic studies is not completely defined, but studies to date suggest that the prevalence of increased diastolic stiffness is high in HFpEF. Several studies using implantable hemodynamic monitors have shown that increased LV diastolic pressures (or their equivalents in pulmonary artery diastolic pressure, left atrial pressures) in patients with HFpEF predict an increase in the frequency of subsequent acute decompensated heart failure.

CLINICAL FEATURES

Diagnostic Criteria

The diagnosis of HFpEF requires that the patient have signs and symptoms of heart failure, an EF greater than 50%, and objective evidence of cardiac dysfunction⁴⁵ (Fig. 27-7). The clinical manifestations of heart failure are similar regardless of the EF. These include reduced exercise tolerance, dyspnea on exertion, orthopnea,

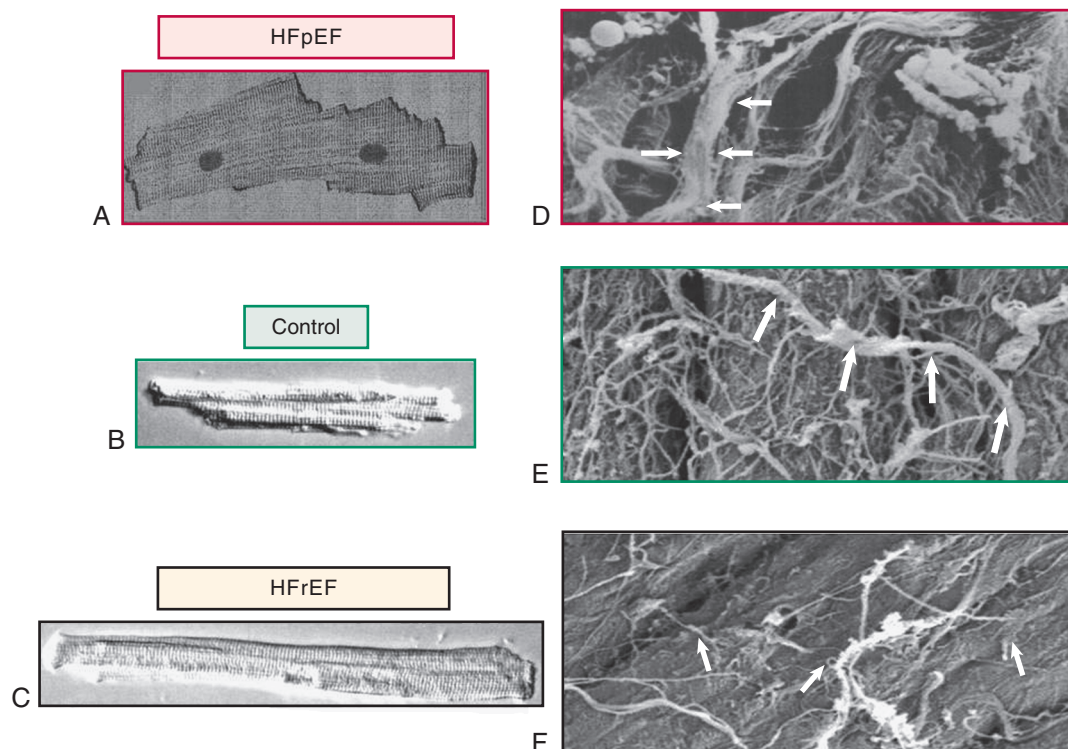

FIGURE 27-6 Changes in cardiomyocyte structure (A-C) and extracellular matrix fibrillar collagen (D-F) in HFpEF (outlined in red) versus HFrEF (outlined in black) versus findings in referent control group (outlined in green). HFpEF is associated with concentric cardiomyocyte remodeling with increased diameter but no change in length and increased fibrillar collagen content, thickness, and number. By contrast, HFrEF is associated with eccentric cardiomyocyte remodeling with increased length but no change in width and fibrillar collagen degradation and abnormal structure and turnover. Arrows indicate fibrillar collagen. (From Aurigemma GP, Zile MR, Gaasch WH: *Contractile behavior in the left ventricle in diastolic heart failure: With emphasis on regional systolic function*. *Circulation* 113:296, 2006.)

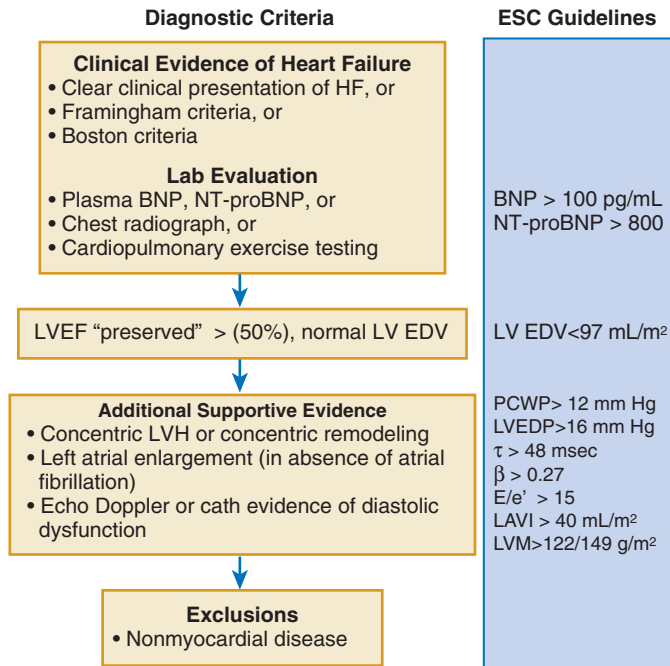

FIGURE 27-7 Diagnostic criteria for HFpEF from the Heart Failure Society of America (HFSA) (left) and the European Society of Cardiology (ESC) (right) guidelines. EDV = end-diastolic volume; LAVI = left atrial volume index; LVEDP = left ventricular end diastolic pressure; LVM = left ventricular mass (index for female/male); PCWP = pulmonary capillary wedge pressure. (From *J Card Fail* 16:475, 2010. Executive Summary; *J Card Fail* 16:e1, 2010. Complete Guideline; and McMurray JJ, Adamopoulos S, Anker SD, et al: ESC guidelines for the diagnosis and treatment of acute and chronic heart failure 2012: The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012 of the European Society of Cardiology. Developed in collaboration with the Heart Failure Association (HFA) of the ESC. *Eur Heart J* 33:1787, 2012.)

paroxysmal nocturnal dyspnea, peripheral edema, and pulmonary congestion apparent on chest radiographs (see also Chapter 23). Although a displaced LV apical impulse and pulsus alternans are presumed to be present only in HFrEF, no clinical features (symptoms, signs, or chest radiography) can be used to reliably distinguish between HFpEF and HFrEF. Thus determination of the EF (usually by echocardiography) is required in patients being evaluated for heart failure. Furthermore, symptoms and signs common in heart failure can have other causes not related to heart failure. For example, exercise intolerance and dyspnea may be due to obesity, pulmonary disease, anemia, or deconditioning. Edema may result from obesity or venous insufficiency. For these reasons, objective demonstration of cardiovascular dysfunction and/or remodeling are necessary to confirm the diagnosis of heart failure. A reduced EF provides this evidence in patients with HFrEF, but in HFpEF the EF is not abnormal (i.e., EF > 50%) and the end-diastolic volume is not increased, so an elevation of the biomarker B-type natriuretic peptide (BNP) (or its N-terminal pro form), abnormal LV diastolic function (determined noninvasively or by direct measurement of LV diastolic pressure), or elevated LA volume is required for the diagnosis of HFpEF. Finally, the diagnosis of HFpEF requires the exclusion of noncardiac causes of symptoms and signs.

Biomarkers. The best-characterized biomarkers in patients with HFpEF are the natriuretic peptides, BNP and N-terminal proBNP (NT-proBNP). Circulating levels of these proteins are elevated in patients with HFpEF as compared with those in persons without heart failure but are lower than in patients with HFrEF (see also Chapter 23). In patients with HFpEF, increased BNP is directly related to LV diastolic filling pressure and end-diastolic wall stress. For any given LV diastolic filling pressure in patients with HFpEF, BNP levels are lower in obese patients and higher in women, older persons, and patients with concomitant pulmonary disease (chronic obstructive disease, pulmonary hypertension, and pulmonary embolus) and renal dysfunction. Because patients with HFpEF have a smaller LV cavity and thicker

LV walls, their end-diastolic wall stress is much lower than in HFrEF, even in the setting of high systolic and diastolic pressures, thus producing a lower stimulus for BNP production. On average, patients with HFpEF presenting with acute decompensation have a BNP value of 100 to 500 pg/mL, versus 500 to 1500 pg/mL in patients with HFrEF. The standard partition values for BNP of 100 pg/mL and for NT-proBNP of 800 pg/mL have been suggested to support the diagnosis of HFpEF. Both baseline values and change from baseline predict cardiovascular outcomes in patients with HFpEF (see Fig. e27-2A, B).^{46,47} Elevation of BNP also indicates increased risk for subsequent events, even in asymptomatic persons. Frequent measurement of BNP and NT-proBNP may be useful in the medical management of HFpEF. Other biomarkers are being developed to aid in the diagnosis and management of HFpEF (see Chapter 23).

Demographic Features

The incidence of HFpEF increases with age, and the condition is more prevalent in women. These demographic features may differ in specific populations. For example, African Americans may develop HFpEF at a younger age. This predilection may be a consequence of more severe comorbid disease, including hypertension, obesity, and diabetes. The antecedent and comorbid conditions are different in HFrEF versus HFpEF. A history of hypertension is present in a majority of patients with HFpEF (80% to 90%), and the disorder may have developed only later in life. Obesity is seen in 30% to 50%, diabetes in 20% to 30%, and atrial fibrillation in up to 20% to 30% of patients. The prevalence of renal disease is high, and it may be progressive. The prevalence of coronary artery disease is 20% to 40%. The presence of each of these comorbid conditions predicts higher morbidity and mortality.⁴⁸ Medications used by patients with HFpEF and those with HFrEF are similar and include diuretics, digoxin, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), beta blocking agents, calcium channel blocking agents, and various other vasodilators and antihypertensive and antiarrhythmic drugs. Although these drugs are not being prescribed as part of a guidelines-based therapeutic approach, they do target the comorbid conditions and the congestive state present in HFpEF.

Comorbid Conditions

Patients with HFpEF and those with HFrEF both frequently have important comorbid diseases. Some of these conditions are antecedent diseases that contribute to the structural and functional changes underlying the pathophysiology of HFpEF and/or precipitate the development of acute decompensation and contribute to morbidity and mortality.⁴⁸ The frequency and severity of comorbid states appear to be higher in HFpEF, owing at least in part to the older age of the patients. Because no treatment approaches specific to HFpEF have been proved to reduce morbidity and mortality, treatment suggestions have focused on comorbid states. Although comorbidity plays a pivotal role in both HFrEF and HFpEF, some investigators have raised the question of whether HFpEF represents true heart failure or just a collection of comorbid conditions.

A number of recent studies have provided data supporting the conclusion that HFpEF is an important, unique clinical syndrome of heart failure.¹ For example, the role of comorbidity in 386 patients with HFpEF was examined in a recent report.⁴⁹ Hypertension, obesity, diabetes, anemia, and renal dysfunction were present in many of these patients. However, even after accounting for age, sex, body size, and comorbidity, patients with HFpEF as a group showed larger LV mass, greater degree of systolic and diastolic dysfunction, more LA enlargement, and increased arterial stiffness. These observations indicate that the comorbid conditions contribute to the development of cardiovascular abnormalities of HFpEF, but the abnormalities are more than what might be expected with these conditions.¹ In addition, other recent analyses of data from RCTs indicated that the prognosis with HFpEF is much worse than that expected with a specific comorbid condition alone. Thus treating the comorbid diseases (especially hypertension) can be expected to delay or prevent the development of HFpEF but may not be adequate therapy for HFpEF

FIGURE e27-2 A, Baseline values of NT-proBNP have significant prognostic value and predict morbidity and mortality outcomes. The higher the baseline value of NT-proBNP, the higher the rate of the primary and heart failure endpoints in the I-Preserve study. **B**, Change from baseline values of NT-proBNP have significant prognostic value and predict morbidity and mortality outcomes. Data from the I-Preserve study indicated that the directional change in NT-proBNP predicted primary and heart failure outcome rates. (**A**, From McKelvie RS, Komajda M, McMurray J, et al: Baseline plasma NT-proBNP and clinical characteristics: Results from the Irbesartan in Heart Failure with Preserved Ejection Fraction trial. *J Card Fail* 16:128, 2010.)

once it develops. Therefore, although comorbid conditions are frequent and important, HFpEF is more than a collection of such conditions.

Aging. The incidence of HFpEF increases with age, probably as a consequence of increased comorbidity in elderly patients and the adverse effects of normal aging on the cardiovascular system. LV diastolic function becomes abnormal with normal aging. This decrement is apparent as slower rates of LV relaxation, changes in the pattern of LV filling, and reduction in the early diastolic annular velocity that slowly progress with age. Thus age correction is used for the normal values of these parameters. In addition, arterial, LV systolic, and LV diastolic stiffness increase with aging. Structural cardiac changes with aging (e.g., increased cardiomyocyte size, increased apoptosis with decreased cardiomyocyte number, altered growth factor regulation, and focal collagen deposition) and functional changes at the cellular level involving blunted beta-adrenergic responsiveness, excitation-contraction coupling, and altered calcium-handling proteins also may contribute to diastolic dysfunction with normal aging.¹² Some evidence suggests that prolonged, sustained endurance training may slow or prevent some of the age-related changes.

Sex. Female sex is a potent risk factor for HFpEF.⁵⁰ The reasons for the female prominence in HFpEF are not entirely clear, but women have more arterial and LV systolic and diastolic stiffness compared with men, and arterial and ventricular stiffness increases more dramatically with age in women. Women are shorter in stature than men, which may enhance the impact of reflected arterial waves on systolic pressure. Finally, these differences also may result from reproductive hormone effects on LV structure and function and response to alterations in load.⁵¹

Hypertension. Hypertension (see also Chapters 43 and 44) is the most commonly associated cardiac condition in patients with HFpEF. Chronically increased systolic blood pressure is an important stimulus for cardiac structural remodeling and functional changes. The resultant hypertensive heart disease is characterized by concentric remodeling or overt LV hypertrophy, increasing arterial and ventricular systolic stiffness, impaired relaxation, and increased diastolic stiffness—all factors linked to the pathogenesis of HFpEF. In the presence of hypertensive heart disease, ischemia produces exaggerated increases in filling pressures, and hypertensive and ischemic heart disease often are present in combination in patients with HFpEF. Determining which factors mediate transition to HFpEF in persons with hypertensive heart disease is an area of active investigation.

Coronary Artery Disease. The reported prevalence of coronary artery disease (see also Chapter 54) or myocardial ischemia in patients with HFpEF varies widely. Although acute ischemia is known to cause diastolic dysfunction, the role of coronary artery disease and ischemia in contributing to chronic diastolic dysfunction and symptoms in patients with HFpEF remains speculative. Despite uncertainty regarding the role of ischemia in the pathophysiology of HFpEF and a lack of data documenting that revascularization improves outcomes in patients with HFpEF, heart failure management guidelines recommend revascularization in those patients with HFpEF in whom “ischemia is felt to contribute to diastolic dysfunction.”^{52,53}

Atrial Fibrillation and Other Rhythm Disturbances. Atrial fibrillation (see also Chapter 38) is recognized as a frequent precipitant of acute decompensation in patients with HFpEF. This is due both to the loss of atrial contraction and to the resulting tachycardia. Whereas atrial fibrillation may cause acute decompensation of heart failure in patients with diastolic dysfunction, diastolic dysfunction (even in the absence of heart failure) results in left atrial enlargement and increases the risk of atrial fibrillation. Thus aging, diastolic dysfunction, atrial fibrillation, and HFpEF are related conditions.

Obesity. Obesity is associated with an increased risk for heart failure regardless of EF. In general, patients with HFpEF are more often obese than patients with HFrEF, and the prevalence of diastolic dysfunction is increased in obese persons. Increased adiposity not only imposes an adverse hemodynamic load on the heart but also is a source of a large number of biologically active peptide and nonpeptide mediators, many linked to chronic inflammation. Increased body mass index (BMI) is a risk factor for hypertension, diabetes mellitus, coronary artery disease, and atrial fibrillation, all of which are associated with HFpEF. Studies using tissue Doppler imaging or invasive LV pressure measurement have reported an association among diastolic dysfunction, elevated filling pressures, and obesity, even in the absence of a heart failure diagnosis.⁵⁴ Dramatic weight loss with

caloric restriction or bariatric surgery is associated with improved LV diastolic function.⁵⁵

Diabetes Mellitus. Diabetes (see also Chapter 61) is a potent risk factor for heart failure, and the prevalence of diabetes is similar in patients with HFrEF and in those with HFpEF, suggesting that diabetes contributes to the pathophysiology of both forms of heart failure. Diabetes predisposes to coronary artery disease, renal dysfunction, and hypertension. In addition, direct effects of diabetes and hyperglycemia on myocardial structure and function have been described. The morphologic changes in the diabetic heart include myocyte hypertrophy, increased extracellular matrix (fibrosis), and intramyocardial microangiopathy. Functional changes include impaired endothelium-dependent and endothelium-independent vasodilation, impaired LV relaxation, increased passive diastolic stiffness, and contractile dysfunction. Mechanisms contributing to structural and functional coronary vascular and myocardial changes include metabolic disturbances, activation of proinflammatory and profibrotic mediators, cardiac autonomic neuropathy, and increases in advanced glycation end-products (AGEs), which promote increased collagen accumulation and stiffness. AGE accumulation may play a role in age-related cardiovascular stiffening. It appears that better control of blood glucose is associated with an improvement in LV diastolic function as measured by noninvasive measures.⁴⁴

Chronic Kidney Disease. The critical impact of renal function on morbidity and mortality in heart failure is well established.⁵⁶ There is no clear difference in severity of renal dysfunction between patients with HFrEF and those with HFpEF.^{14,57} Furthermore, the incidence of worsening renal function during heart failure therapy is similar in patients with HFrEF and in those with HFpEF. Although the prevalence of renal vascular disease in heart failure has been poorly delineated, evaluation of the renal arteries should be considered in patients presenting with the triad of hypertension, renal dysfunction, and HFpEF.

Sleep Apnea. Obstructive sleep apnea (see also Chapter 75) is common in patients with HFpEF, can contribute to symptom severity, and is likely to promote progression of heart failure. Central sleep apnea can occur in association with severe HFpEF.

Pulmonary Hypertension. Most patients with HFpEF have at least some degree of pulmonary hypertension, with pulmonary artery systolic pressures commonly greater than 40 mm Hg.⁵⁸ This is at least partly a consequence of the elevated LV filling pressures, with resulting increased pulmonary venous pressure.²⁶ In addition, the pulmonary vascular resistance may be increased by reactive pulmonary arterial vasoconstriction. This reactive process may be most apparent during exercise. In some patients, chronic pulmonary venous hypertension causes pulmonary vascular remodeling (congestive pulmonary vasculopathy), leading to irreversible pulmonary hypertension. The presence of increased pulmonary artery pressures has prognostic implications and is associated with higher morbidity and mortality rates.

Rarer Causes of Heart Failure with Preserved Ejection Fraction

Hypertrophic cardiomyopathy (see Chapter 66), infiltrative cardiomyopathies such as amyloidosis (see Chapter 65), valvular disease (see Chapter 63), and constrictive pericarditis (see Chapter 71) should always be considered in patients with HFpEF. However, these diseases account for a small minority of cases of HFpEF. The clinical presentation and echocardiographic appearance in older persons with HFpEF may be identical to those in patients previously labeled as having restrictive cardiomyopathy. An important consideration in patients with previous malignancy treated with mediastinal irradiation is radiation-induced heart disease (see Chapter 69). Radiation can cause pericardial and concomitant myocardial damage, and persistent heart failure after pericardiectomy is frequent because of concomitant myocardial disease. Concomitant valvular disease and premature coronary artery disease also are common in patients with previous mediastinal irradiation and may contribute to the pathophysiology of HFpEF in patients with radiation-induced heart disease.

Acute Decompensated Heart Failure in Patients with HFpEF (See also Chapter 24)

Acute decompensated heart failure (ADHF) is a frequent outcome in patients with heart failure and may require urgent treatment in the hospital, emergency department, or outpatient office setting. A

majority of patients hospitalized for ADHF have preexisting heart failure; at least 50% of these patients have HFpEF. Rehospitalizations are frequent, but many patients with HFpEF may be minimally symptomatic between episodes of ADHF. In the vast majority, ADHF is due to pulmonary congestion that accompanies increases in LV diastolic filling pressure⁵⁹ (Fig. 27-8A). Both baseline LV diastolic filling pressure and changes in filling pressure are sensitive predictors of future ADHF events (Fig. 27-8B). ADHF in patients with HFpEF can result from increased filling pressure with or without significant changes in LV diastolic volume.⁶⁰ In addition, increased LV diastolic pressure and volume can result from increases in total intravascular volume or shifts of intravascular volume due to splanchnic vasoconstriction. The mechanisms responsible for these changes include worsening diastolic dysfunction, increased neurohormonal activation, and poorly controlled comorbid disease. In patients with HFpEF, arterial hypertension, myocardial ischemia, and diabetes mellitus can act on preexisting structural and functional abnormalities to cause deterioration in LV diastolic function and precipitate ADHF. Atrial arrhythmias can result in loss of atrial function and stimulate compensatory increases in diastolic filling pressure in order to maintain LV filling and maintain cardiac output. Decreased LV diastolic function and abnormal LA function can result in neurohormonal activation, which plays an important role in ADHF by producing increased sodium and water retention, increased venous return, increased splanchnic tone, and arterial vasoconstriction. Even after normal volume status is restored and neurohormonal activation is suppressed, the inciting

comorbid condition may remain and can influence the subsequent clinical course. This ongoing process may contribute to a high rate of non-heart failure–related rehospitalizations after a heart failure episode.^{19,61}

Clinical Assessment of Cardiovascular Structure and Function

Assessment of LV structure and function is an essential step in the clinical evaluation of patients with suspected HFpEF in order to establish diagnosis, assess prognosis, and monitor effectiveness of treatment.²⁸ In addition, changes in structure and function contribute to the pathophysiologic mechanisms that underlie the development of HFpEF. Although echocardiography remains the most widely used noninvasive clinical imaging technique, evaluation may be supplemented or enhanced by other imaging techniques such as magnetic resonance imaging (MRI) and computed tomography (CT) scanning. As in the case of patients with HFrEF, the structural and functional characteristics of patients with HFpEF have some features that all (or nearly all) patients share in common and others that demonstrate some variability in prevalence.

Left Ventricular Structure

Left Ventricular Volume

Most (>90%) patients with HFpEF have normal LV chamber dimension, area, and volume; up to 5% of patients have a mild increase in LV volume above the upper normal partition value of 75 mL/m².^{10,62,63} In addition, in many patients with HFpEF, LV volumes are small, contributing to a limitation in stroke volume and cardiac output response to exercise. An LV volume less than 75 mL/m² is one of the guidelines-based diagnostic criteria for HFpEF.

Left Ventricular Mass

LV mass is increased and reaches criteria for LV hypertrophy in roughly 30% to 50% of patients with HFpEF.⁸ Some evidence suggests that the prevalence of LV hypertrophy may be higher among African American patients and women with HFpEF.^{64,65} When present, LV hypertrophy is associated with significantly worse prognosis. Even in those patients who do not meet criteria for LV hypertrophy, structural remodeling may have developed, evidenced as concentric remodeling and cardiomyocyte hypertrophy (see Fig. 27-6).

Left Ventricular Geometry

The ratio of LV mass to volume (M/V), or of LV wall thickness to LV internal dimension (relative wall thickness [RWT]), describes the geometry of the left ventricle.⁹ When mass or thickness is increased relative to (or out of proportion with) volume or dimension, the resultant changes are termed *concentric remodeling*. Concentric remodeling can occur even in the absence of frank LV hypertrophy in approximately 20% to 30% of patients with HFpEF and is associated with a 25% to 35% higher risk of heart failure events.

Left Ventricular Function

Diastolic Properties

Patients with HFpEF may have abnormalities in all aspects of diastolic function. These may include a delayed and slow relaxation, decreased recoil, slow and incomplete early filling, increased filling during atrial contraction, and decreased distensibility. The methods necessary to individually quantify these properties and the mechanisms that cause them to become abnormal were described earlier in the section on pathophysiology. However, echocardiographic techniques can be used to assess these properties in a combinatorial fashion in order to characterize a diastolic function grade of 0 (normal), 1 (abnormal relaxation), 2 (pseudonormalized), 3a (reversible restrictive), or 3b (irreversible restrictive)²⁸ (Fig. 27-9). This echocardiographic and Doppler echo–based grading scale is the most common clinical method of assessing severity of diastolic dysfunction.

Grade 1 diastolic dysfunction is characterized by the presence of mild diastolic dysfunction with slow LV relaxation. The early diastolic pressure

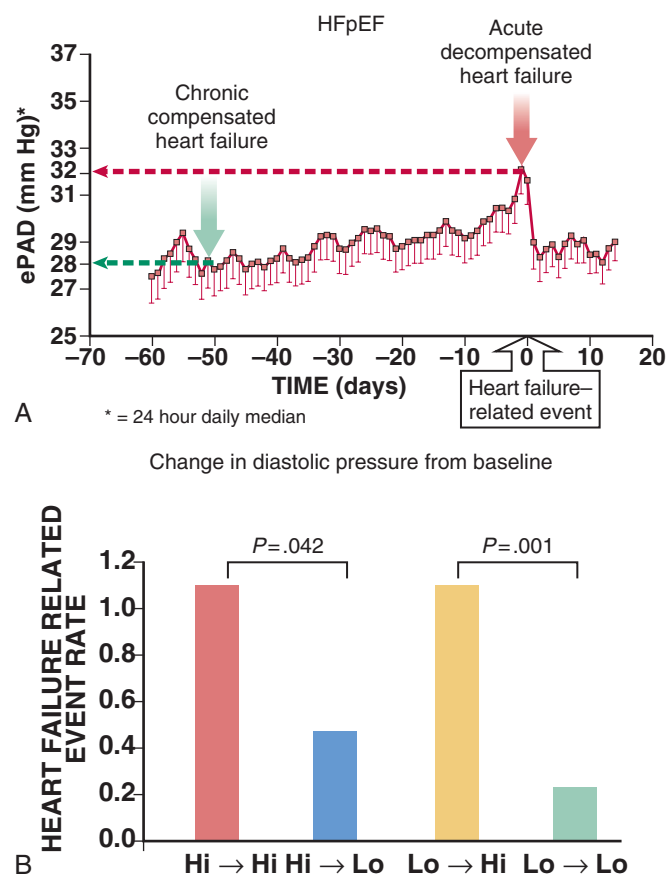

FIGURE 27-8 **A**, Patients with HFpEF have increased LV diastolic pressure (indexed here as ePAD) even when considered in good compensation by their physician and experience further increases in pressure with the development of ADHF necessitating hospital admission **B**, Both baseline LV diastolic filling pressure and changes in filling pressure are sensitive predictors of future ADHF events. (**A**, From Zile MR, Bennett TD, St John Sutton M, et al: Transition from chronic compensated to acute decompensated heart failure: Pathophysiological insights obtained from continuous monitoring of intracardiac pressures. *Circulation* 118:14331, 2008; **B**, from Stevenson LW, Zile M, Bennett TD, et al: Chronic ambulatory intracardiac pressures and future heart failure events. *Circ Heart Fail* 3:580, 2010.)

FIGURE 27-9 Evaluation of diastolic function based on the left ventricular filling dynamics determined by Doppler measurement of mitral valve flow velocity and tissue Doppler measurement of mitral annular velocity. Normally the early diastolic mitral flow velocity (E) and the mitral annular velocity (e') are brisk and occur nearly simultaneously. With mild diastolic dysfunction (impaired relaxation pattern—grade 1) the mitral E velocity is reduced and is less than the late diastolic mitral flow velocity (A). The E deceleration time (DT) is increased. With more severe diastolic dysfunction (grades 2 and 3), E is increased and DT is reduced. In these patterns, e' is reduced and delayed relative to the mitral E. (From Little WC, Oh JK: Echocardiographic evaluation of diastolic function can be used to guide clinical care. *Circulation* 120:802, 2009.)

gradient between the left ventricle and the left atrium that accelerates transmitral flow into the left ventricle is decreased because there is no increase in LA pressure, and early LV diastolic pressure is higher owing to abnormal relaxation.²⁸ This results in a decrease in both the early transmitral flow velocity E and early tissue velocity, e' , and an increase in the importance of late diastolic mitral flow velocity (A), the transmitral velocity resulting from atrial contraction, producing an E/A ratio less than 1. The delayed relaxation results in a prolongation of E wave deceleration time (DT) and may be associated with a mid-diastolic peak of mitral flow (L wave).⁶⁶ The contribution to LV filling produced by atrial contraction is increased. This filling pattern has been termed an impaired relaxation pattern or grade I diastolic dysfunction.⁶⁷ In most patients with impaired relaxation pattern, the mean LA pressure is not elevated despite an increased LV end-diastolic pressure, which is maintained by a vigorous atrial contraction.

Grade 2 diastolic dysfunction occurs when progressive worsening of diastolic dysfunction is associated with an increase in LA pressure and there is restoration of the early diastolic pressure gradient despite increased early diastolic LV pressures. These changes result in a return of the E wave to the normal range (pseudonormal mitral inflow pattern). Displacement of the left ventricle onto a steeper portion of the pressure-volume curve results in a shortening of the DT. With slower relaxation, the e' is delayed, occurring after the E. This indicates that the left ventricle is not expanding symmetrically in diastole, but that propagation of filling to the apex and longitudinal expansion occurs slowly after the left ventricle is filled by the movement of blood from the left atrium into the LV inflow tract. In the presence of slow relaxation, e' does not occur during the time of the LA-to-LV pressure gradient, so e' is reduced and becomes almost independent of LA pressure.²⁹ Both the low mitral annular e' and the delay in e' relative to E correlate with increased time constant of LV isovolumetric pressure decline.²⁹ Thus the pseudonormal mitral inflow pattern is distinguished from normal by a reduced and delayed e' and increase in the E/ e' ratio.

Grade 3 diastolic dysfunction occurs when severe diastolic dysfunction causes a markedly slowed relaxation and elevated LA pressure; the E increases further, DT becomes very short, and e' is further reduced and delayed resulting in a marked elevation of E/ e' .³⁰ With severe diastolic dysfunction, the late diastolic annular velocity (a') also may be reduced, and pulmonary venous systolic forward flow velocity is reduced as well, to less than diastolic forward flow velocity. With grade 3, if a Valsalva maneuver causes a reduction of E wave velocity, the condition is designated *reversible*; if Valsalva does not change E, it is designated *irreversible*.

NONINVASIVE ESTIMATION OF LEFT VENTRICULAR DIASTOLIC FILLING PRESSURE. Knowledge of LV diastolic pressure in patients

with known or suspected HFpEF is important for establishing diagnosis, predicting prognosis, and directing therapy. However, because direct measures of diastolic pressure are invasive and not suitable for repeated measures, noninvasive echo and echo Doppler measurements have been developed and clinically applied. The measurements used in the diastolic grading system also can be used to estimate LV diastolic filling pressures and to follow progression of disease and response to therapy. Pseudonormalized and restricted filling patterns indicate the presence of both diastolic dysfunction and elevated LA pressure.³⁰ By contrast, the impaired relaxation pattern indicates diastolic dysfunction without a marked elevation in LA pressure.

Additional echo Doppler measurements that may reflect diastolic filling pressures include estimation of peak RV systolic pressure (PRVSP) from the tricuspid regurgitation velocity and LA volume.²⁶ The most common cause of increased pulmonary artery systolic pressure in HFpEF is an elevation of LA pressure, and the echocardiographic parameters best correlated with PRVSP are DT and E/ e' .⁵⁸ Diastolic dysfunction grade and PRVSP estimate instantaneous diastolic pressure. Changes in LA volume reflect longer-term changes in LV filling pressures.^{2,58,65} LA volume is dependent on the product of diastolic pressure and time, so the longer pressures are increased and the higher they are increased, the larger the LA volume. Abnormal diastolic dysfunction grade, increased PRVSP, and increased LA volume are highly prevalent in patients with HFpEF and have significant prognostic value (Fig. 27-10).

All of the foregoing measures are useful in identifying patients with or without elevations of LA pressure. However, the most commonly used and easily interpretable parameter to estimate LA pressure is the E/ e' ratio.²⁸ E/ e' has been found to correlate with pulmonary capillary wedge pressures (PCWPs) in a wide range of patients studied in multiple laboratories.^{67,68} An E/ e' greater than 15 has been found to clearly indicate elevated PCWP, whereas E/ e' less than 8 is associated with normal LA pressure (see Fig. 27-4).⁶⁷ The cut-off value of E/ e' of 15 to recognize elevated LA pressure was obtained using e' velocity from the medial mitral annulus. Because e' velocity from the lateral annulus usually is higher than the medial e' velocity, the cut-off value should be adjusted to 12 if the lateral annular velocity is used. An average of the medial and lateral annular velocities has been recommended.⁶⁷ In some situations, however, E/ e' may not provide an accurate assessment of PCWP.

The clinical settings in which this application of E/ e' may be inaccurate are described in an online supplement for this chapter (Limitations in Use of E/ e').²⁸

PREVALENCE AND PROGNOSIS FOR DIASTOLIC DYSFUNCTION IN HFPEF. The frequency distribution of diastolic dysfunction grade, increased PRVSP, and LA volume varies according to the characteristics of the population studied, that is, the patient's level of hemodynamic compensation and severity of disease; a truly normal diastolic function profile, however, is uncommon in patients with HFpEF.⁶⁹ For example, an abnormal diastolic dysfunction grade was found in 60% to 70% of the patients enrolled in the I-Preserve and CHARM studies; LA enlargement was present in 66%, and either diastolic dysfunction of grade II to IV or LA enlargement was found in 85%.

Echocardiographic findings related to diastolic function provide important prognostic information in a wide variety of patient populations. A normal filling pattern in community-dwelling subjects indicates an excellent prognosis.⁷⁰ By contrast, an abnormal filling pattern along with progressively worsening abnormalities of LV filling pattern (impaired relaxation versus pseudonormalized and restricted filling) indicates subjects with a progressively increased risk of subsequent mortality. The stage of diastolic dysfunction correlates with the impairment of exercise capacity in patients without myocardial ischemia, whereas LV EF does not.⁷¹ In patients with heart failure, the stage of diastolic dysfunction is a stronger predictor of mortality than EF.⁷²

Limitations in Use of E/e'

Described here are several clinical situations in which E/e' may not provide an accurate assessment of PCWP.¹ First, in a normal heart, e' occurs coincidentally with E and responds to changes in LA pressure. For example, E/e' was not increased but may decrease in response to massive fluid loading in normal experimental animals.² However, LA pressure is rarely elevated in patients with a normal heart.³ Thus the failure of E/e' to recognize elevated left atrial pressures in normals is of little clinical importance. Second, E/e' does not increase in patients with constrictive pericarditis despite elevated PCWPs.⁴ In fact, the median e' increases as constriction becomes worse, which results in a decrease in E/e' as constriction gets more severe and diastolic filling pressure increases (annulus paradoxus). If the patient has clinical signs of heart failure, especially with increased jugular venous pressure, a normal or increased median e' velocity strongly suggests constrictive pericarditis. Third, E/e' may not provide an estimate of LA pressure in patients with mitral stenosis or mitral regurgitation, especially without a reduction in EF.^{5,6} The mitral

annular velocity should not work as well in patients with aortic or mitral valve replacement and mitral annulus calcification. However, this issue has not been systematically evaluated. Fourth, although E/e' correlates with LA pressure in patients with hypertrophic cardiomyopathy, the substantial scatter of data limits its use alone in an individual patient.⁷

A short DT indicates an increased LV operating stiffness, is a hallmark of restrictive filling pattern, and connotes poor prognosis in patients with a history of myocardial infarction, persons with dilated cardiomyopathy, heart transplant recipients, and patients with hypertrophic or restrictive cardiomyopathy.⁶⁷ Both pseudonormalized and restricted filling patterns are associated with a four-fold increase in

the risk of death in patients with heart failure and coronary artery disease.⁷³ Similarly, an elevated E/e' indicates a poor prognosis in a wide variety of patients.⁶⁷ Finally, in patients with HFpEF, abnormal diastolic function measured as diastolic dysfunction grade or LA enlargement also predicts marked increase in morbidity and mortality events (see Fig. 27-10).

Systolic Properties

Global LV systolic chamber properties are normal at rest in patients with HFpEF. By definition, patients with HFpEF have a normal (or near-normal) EF. In addition, patients with HFpEF have normal dP/dt_{max} , stroke volume, stroke work, and preload recruitable stroke work. Furthermore, indices of chamber contractility such as LV end-systolic elastance are actually increased in HFpEF, matching the increased arterial elastance, so that the coupling between these properties is preserved.^{74,75} By contrast, in HFrEF, LV systolic elastance is reduced and arterial elastance is elevated so that ventricular-vascular coupling is impaired. In fact, the presence of a normal EF indicates that the coupling of the left ventricle and arterial system is nearly optimal to convert the energy of contraction into the stroke work.⁷⁶ Thus arterial vasodilation improves LV systolic performance in HFrEF but not in HFpEF.⁷⁷ Because indices of end-systolic elastance are altered by remodeling, chronic changes in chamber contractility should be normalized to the LV mass/end-diastolic volume ratio. With this adjustment, elastance measurements in patients with HFpEF are normal in the resting state.

Although global LV systolic performance is normal in HFpEF, indices of myocardial contractile function such as midwall shortening may be reduced.⁷⁸ This effect appears to be offset by concentric remodeling or hypertrophy. In addition, many patients with HFpEF have reduced LV longitudinal shortening velocity, strain, and strain rate and reduced apical systolic torsion. Enhanced circumferential shortening offsets the impact of these regional abnormalities on LV ejection performance. Although these abnormalities of regional performance occur during systole, their greatest impact may occur during diastole. Decreased long-axis shortening and torsion lessen the diastolic recoil of elastic elements compressed during ejection, thereby diminishing the ability of the left ventricle to function as a suction pump, so that LV filling becomes more dependent on LA pressure. Thus these regional systolic abnormalities result in significant increases in pulmonary venous filling pressures and symptoms of congestion and volume overload.

During exercise, patients with HFpEF have a decreased ability to augment indices of LV chamber systolic performance, function, and contractility.

Additional material on exercise tolerance testing in these patients is presented in an online supplement for this chapter (Assessment of Exercise Capacity in Heart Failure with Preserved Ejection Fraction).

This decrement in adaptability to the demands of exercise may result from abnormalities in diastolic function, chronotropic incompetence, decreased response to sympathetic and renin-angiotensin-aldosterone system (RAAS) stimulation, or exaggerated increase in afterload. For example, decreased diastolic distensibility prevents the left ventricle from recruiting Starling forces in patients with HFpEF; thus abnormal diastolic function limits augmentation of systolic properties. In addition, because hypertensive heart disease is common in HFpEF, many patients with HFpEF have limited exercise tolerance because of the exaggerated increase in blood pressure that accompanies exercise; this increased afterload prolongs relaxation and decreases diastolic distensibility. Finally, because systolic and arterial elastances are increased in HFpEF, exercise-induced increases in RAAS and sympathetic stimulation are unable to augment systolic properties sufficiently to maintain adequate stroke volume.⁷⁹

THERAPY

A large number of prospective RCTs have been conducted in patients with HFrEF, with findings used to guide evidence-based

Assessment of Exercise Capacity in Heart Failure with Preserved Ejection Fraction

Patients with HFpEF have a symptomatic disability that is evidenced as a reduction in exercise tolerance. This disability can be objectively assessed using a 6-minute hall walk, a standard exercise treadmill, and cardiopulmonary exercise testing. These tests have important diagnostic utility in patients with HFpEF, particularly if the cause of the exercise intolerance is unclear or the diagnosis is otherwise uncertain. In addition, cardiopulmonary exercise testing can identify poor motivation, deconditioning, and pulmonary disease as alternate explanations for dyspnea ([see also Chapter 13](#)). These objective measures of exercise tolerance are similarly impaired in HFpEF and HFrEF, with equivalent decreases in time and distance on the treadmill and decreases in MVO_2 . Exercise testing can identify factors that contribute to the clinical syndrome of HFpEF and can potentially be modified. For example, an exaggerated increase in systolic arterial pressure during exercise can cause load-dependent diastolic dysfunction. Pharmacologic reduction of this response can improve exercise tolerance in HFpEF. Because augmentation of the stroke

volume is limited in HFpEF, the cardiac output is highly dependent on increased heart rate. In patients with HFpEF who display an inadequate increase in heart rate with exercise (chronotropic incompetence), limiting beta-adrenergic blocking agents or even rate-responsive pacing may improve exercise tolerance. Finally, exercise training improves exercise tolerance in HFpEF by reversing some of the effects of deconditioning. In addition, exercise training also may improve indices of diastolic function. Changes in exercise capacity that limit functional capacity can be assessed using a variety of instruments measuring quality of life. A number of quality-of-life surveys have been validated and used in studies in HFpEF. These include the Quality of Life in Severe Heart Failure Questionnaire (QLQ-SHF), the Chronic Heart Failure Questionnaire (CHQ), the Left Ventricular Dysfunction Questionnaire (LVD), and the Minnesota Living with Heart Failure Questionnaire (MLHFQ). The three most commonly used are the QLQ-SHF, the CHQ, and the MLHFQ.¹

therapy. By contrast, such evidence is lacking for patients with HFpEF: “No treatment has yet been shown, convincingly, to reduce morbidity or mortality in patients with HFpEF.”⁸⁰ Therapies with proven benefit in HFrEF, including pharmacologic regimens of ACE inhibitors, ARBs, beta blocking agents, or aldosterone blocking agents, as well as placement of implantable defibrillators and cardiac resynchronization, have not shown any clear benefit in HFpEF, or data from RCTs are not available for HFpEF. Nevertheless, the practical clinical approach presented in this section will reduce symptoms, prevent acute decompensation, and improve exercise tolerance.

Summary of Randomized Controlled Trials

Four large RCTs have enrolled patients with HFpEF (with EF entry criteria ranging from >35% to >50%), with time to first hospitalization or death as the primary endpoint. Each of these RCTs had a neutral outcome (Fig. 27-11).

The Digitalis Investigators Group (DIG) Trial included a separate cohort of 988 patients with ambulatory HFpEF (EF >45%) in normal sinus rhythm. In this HFpEF group, digoxin did not alter the primary endpoint of heart failure–related hospitalization or cardiovascular mortality but did reduce the number of such hospitalizations.⁸¹ Total cardiovascular hospitalizations were not reduced, however, because of an increased rate of admissions for unstable angina, which completely negated the benefit of reduced heart failure hospitalizations.⁸²

The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) program of trials evaluated the ARB candesartan in patients with heart failure. In the CHARM-Preserved arm,⁸³ patients with heart failure and an EF above 40% were randomly assigned to receive candesartan or placebo in addition to standard therapy. Fewer patients in the candesartan group than in the placebo group reached the primary endpoint of cardiovascular death or heart failure–related hospitalization, a finding that reached statistical significance only after adjustment for small

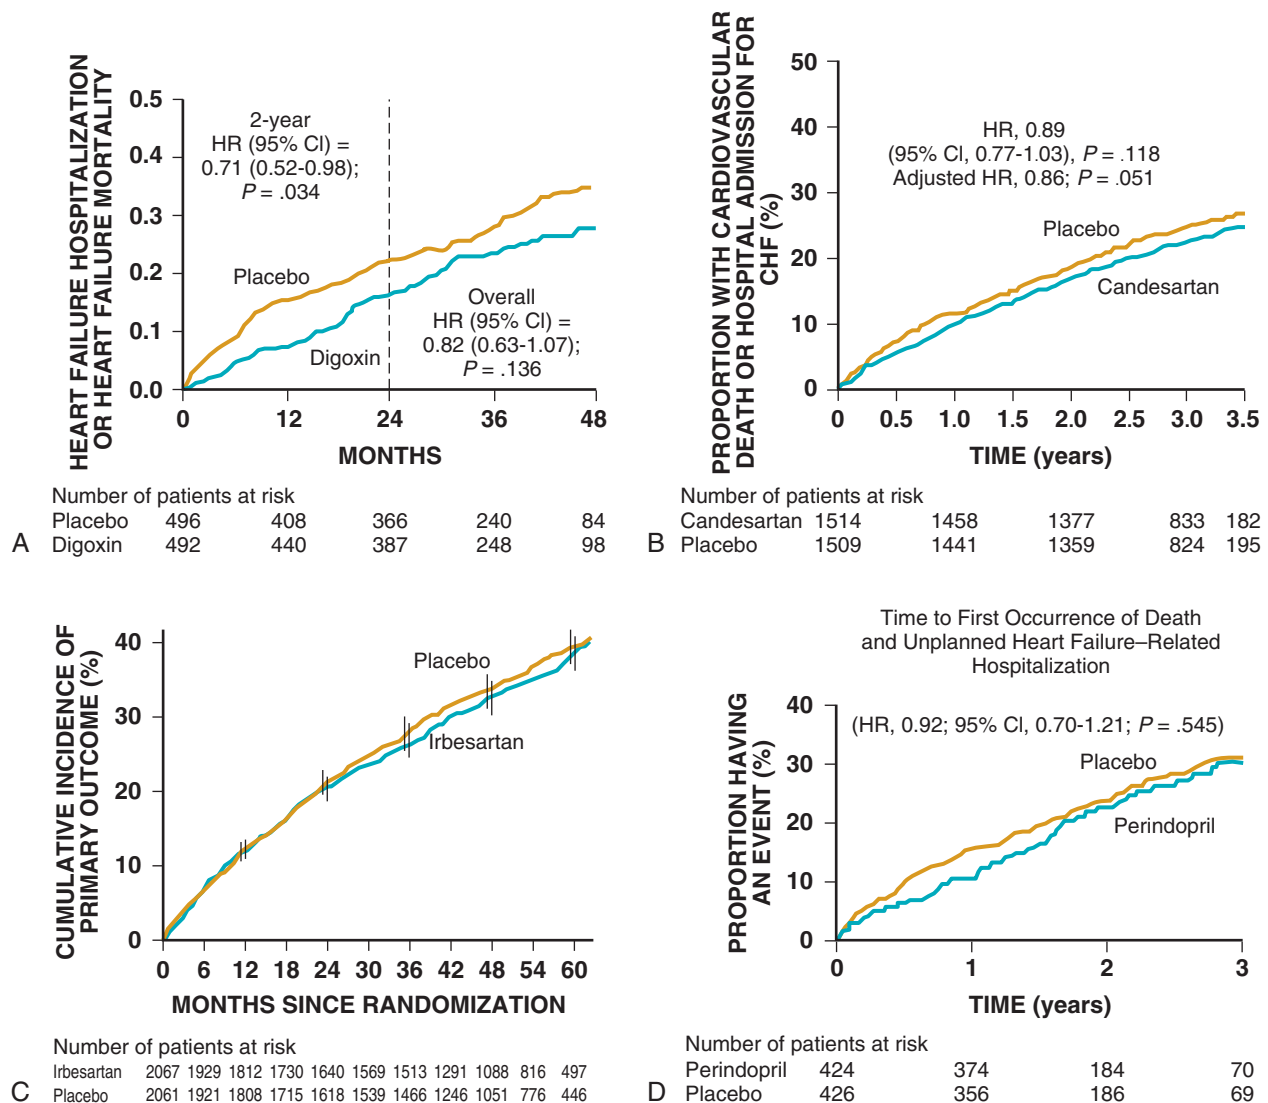

FIGURE 27-11 Kaplan-Meier survival curves for the primary endpoint in the Digitalis Investigators Group (DIG) Trial substudy of patients with heart failure with normal ejection fraction (HFnlEF) (A), the Candesartan in Heart Failure: Assessment of Reduction in Morbidity and Mortality (CHARM)-preserved trial (B), the Irbesartan in Patients with Heart Failure and Preserved Ejection Fraction (I-Preserve) trial (C), and the Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial (D). See text for discussion. CHF = chronic heart failure; CI = confidence interval; HR = hazard ratio. (A, From Ahmed A, Rich MW, Fleg JL, et al: Effects of digoxin on morbidity and mortality in diastolic heart failure: The ancillary digitalis investigation group trial. *Circulation* 114:397, 2006; B, from Yusuf S, Pfeffer MA, Swedberg K, et al: Effects of candesartan in patients with chronic heart failure and preserved left-ventricular ejection fraction: The CHARM-preserved trial. *Lancet* 362:777, 2003; C, from Massie BM, Carson PE, McMurray JJ, et al: Irbesartan in patients with heart failure and preserved ejection fraction. *N Engl J Med* 359:2456, 2008; D, from Cleland JG, Tendera M, Adamus J, et al: The perindopril in elderly people with chronic heart failure (PEP-CHF) study. *Eur Heart J* 27:2338, 2006.)

differences in baseline characteristics. Furthermore, there was no impact on mortality.

In the Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial, patients older than 70 years of age with HFpEF (EF >0.45) with echocardiographic evidence of diastolic dysfunction were randomly assigned to receive perindopril (an ACE inhibitor) or placebo.⁸⁴ The primary endpoint was a composite of all-cause mortality or unplanned heart failure–related hospitalization. Both enrollment and event rates were lower than anticipated, and a high rate of cessation of blinded therapy, with crossover to open-label ACE inhibitor use, was reported for both groups. These factors limited the power of the study, which did not show significant reduction in the primary endpoint. Some trends toward benefit, primarily driven by reduction in heart failure–related hospitalizations, were observed in a post hoc analysis of the results at 1 year, when crossover therapy rates were lower.

The Irbesartan in Heart Failure with Preserved Ejection Fraction Study (I-Preserve) tested the ARB irbesartan in 4128 patients who were at least 60 years of age and had New York Heart Association (NYHA) class II, III, or IV heart failure, with an EF above 45%.⁸⁵ The primary outcome was death from any cause or hospitalization for a cardiovascular cause (heart failure, myocardial infarction, unstable angina, arrhythmia, or stroke). Secondary outcomes included death from heart failure or hospitalization for heart failure, death from any cause and from cardiovascular causes, and impaired quality of life. Irbesartan had no effect on any of the prespecified outcomes.

The Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS) trial tested the effect of the beta-selective blocking agent nebivolol in patients with heart failure without an EF requirement.⁸⁶ Nebivolol also has vasodilator properties thought to be related to its effects on nitric oxide release. A modest but significant reduction was observed in the primary endpoint of all-cause mortality or cardiovascular hospitalizations, driven primarily by the effect on hospitalizations. Prespecified subgroup analysis in patients with EF above versus below 35% did not detect any trends toward reduced benefit in those with higher EF. Unfortunately, very few patients with EF above 50% were included in the trial. Thus it is not possible to draw conclusions about the benefit of beta blocking agents in HFpEF from this study. However, analysis of a large observational study found no mortality benefit of treatment with a beta blocking agent after a hospitalization for heart failure in patients with EF above 40%.⁸⁷ By contrast, in patients with EF below 40%, a clear mortality benefit was found, consistent with the results of randomized trials of beta blocking agents with HFrEF.

Phase II Studies of Novel Pharmacologic Treatment of HFpEF

Several novel approaches to the pharmacologic treatment of HFpEF are being developed and examined in phase II and phase III trials. These include treatment with the aldosterone antagonist spironolactone; the angiotensin receptor neprilysin inhibitor (ARNI) LCZ696; and PDE-5 inhibitor sildenafil.

Prospective comparison of ARNI versus ARB on Management of Heart Failure with Preserved Ejection Fraction (PARAMOUNT) was a phase II, randomized, parallel group, double-blind, multicenter trial in patients with NYHA class II or III HFpEF (EF >45%) and NT-proBNP level greater than 400 pg/mL.⁸⁸ LCZ696 is an angiotensin receptor and neprilysin inhibitor.⁸⁸ A cohort of 149 patients were assigned to receive therapy with LCZ696 (200 mg twice daily) and another 152 patients to receive valsartan (160 mg twice daily) for 36 weeks. The primary endpoint was change in NT-proBNP from baseline to 12 weeks. At 12 weeks, LCZ696 significantly reduced NT-proBNP by approximately 15%, compared with valsartan (no significant change; for difference in response, $P = .005$). At 36 weeks, LCZ696 significantly reduced LA volume by approximately 5% compared with valsartan (no significant change; for difference in response, $P = .003$). LCZ improved NYHA functional class versus valsartan ($P = .05$). LCZ696 was well tolerated, with adverse effects similar to those for valsartan. Whether these findings will translate into improved outcomes need to be tested in a large randomized trial.

The effects of the phosphodiesterase-5 inhibitor sildenafil (50 mg three times daily) were examined in 44 patients with HFpEF (heart failure signs and symptoms, diastolic dysfunction, EF of 50% or

greater, and pulmonary artery systolic pressure more than 40 mm Hg) versus placebo in a single-center study.⁸⁹ At 6 and 12 months, sildenafil treatment resulted in a decrease in mean pulmonary artery pressure, improved RV function, reduced lung water content, improved alveolar-capillary gas conductance, and a 16% reduction in pulmonary wedge pressure. In the RELAX trial, however, when sildenafil was studied in a larger group of patients with HFpEF without a requirement for having pulmonary hypertension, no improvement was observed in exercise tolerance or diastolic function.⁹⁰

The effects of spironolactone on clinical outcomes and LV structure and function have been examined in a retrospective study and a small prospective study. To date, spironolactone has been shown to improve indices of diastolic function but not clinical outcomes. A large RCT (TOPCAT [ClinicalTrials.gov identified: NCT00094302]) has completed recruitment and is nearing completion.

Management of Heart Failure with Preserved Ejection Fraction

The practical clinical management of HFpEF has three main components. The first aspect of management is reduction and prevention of pulmonary and peripheral venous congestion. These objectives can be accomplished with fluid and sodium restriction, judicious use of diuretics and nitrates, selective application of neurohormonal modulation, and appropriate remote monitoring–based tailored care. The second component is aggressive treatment of antecedent and comorbid diseases. Strategies include controlling blood pressure at rest and modifying blood pressure response to exercise, controlling glucose, treating and preventing ischemia, and maintaining adequate renal function. The third component of management is optimization of cardiac functional status—to prevent excessive tachycardia or bradycardia, to match heart rate to metabolic needs, to maintain or restore normal sinus rhythm, and to control ventricular response rate during atrial arrhythmias.

Nonpharmacologic Therapy

General measures that may be used in the management of patients with HFpEF include attention to diet and lifestyle, avoidance or reversal of obesity, increase in exercise, adherence to management strategies, daily monitoring of weight, patient education, and close medical follow-up using facilitated home management. Sodium restriction to less than 2 g/day may be effective. Excessive fluid volume intake should be avoided but balanced with respect to renal function (see further on). If sodium and fluid restriction together with diuretic use results in decreased glomerular filtration rate (GFR), optimal volume status may be characterized by some amount of permissive peripheral edema.

Small randomized studies have demonstrated that exercise training in patients with HFpEF improves exercise tolerance, although the effects on indices of diastolic function have been variable.⁹¹⁻⁹⁴

Treatment of Comorbid Conditions

Patients with HFpEF frequently have important antecedent and comorbid diseases that can contribute to the development of HFpEF, affect its clinical severity, and precipitate decompensation. Accordingly, treating comorbid illnesses is an important element of management of patients with HFpEF. The most important and frequent comorbid conditions include arterial hypertension, obesity, diabetes, chronic kidney disease, obstructive sleep apnea, and anemia.

Most patients (>85%) with HFpEF have either current or previous hypertension. Untreated hypertension is a strong risk factor for the development of heart failure. Treatment of systolic hypertension in elderly patients (who have the highest risk for development of HFpEF) is associated with a more than 50% reduction in the frequency of heart failure.⁹¹ Evidence-based therapy of HFpEF therefore includes control of systolic hypertension. The goal of therapy is systolic arterial pressure below 140 mm Hg and diastolic blood pressure below 90 mm Hg. Because of the arterial stiffening present in many patients, especially the elderly, adequate blood pressure control may be difficult to achieve. These patients also are prone to the development of orthostatic hypotension. Adequate treatment of patients with

hypertensive heart disease includes not only control of the blood pressure but also prevention of LV hypertrophy or measures to induce regression of the hypertrophy, which will lead to reduced morbidity and mortality, improved exercise tolerance, and improved diastolic function.⁹⁵

Diabetes and obstructive sleep apnea are common in HFpEF and are associated with worse outcomes. The available data suggest that treatment of diabetes and sleep apnea improves diastolic function and clinical status in patients with HFpEF. Thus use of proven therapies for these conditions is an important component of managing patients with HFpEF.

Obesity is highly prevalent among patients with HFpEF. For example, the large ADHERE registry found that more than half of patients weigh more than 172 pounds, and one quarter weigh more than 213 pounds. This is an impressive finding, because a majority of the patients are elderly women.⁹⁶ Obesity itself impairs exercise intolerance but also contributes to the development of hypertension, diabetes, and sleep apnea. BMI is an important predictor of outcomes in patients with HFpEF.⁹² Weight loss produced by bariatric surgery or caloric reduction improves indices of diastolic function. Thus weight loss through diet or bariatric surgery may represent an important management strategy for obese patients with HFpEF.

Chronic kidney disease frequently accompanies HFpEF and contributes to decompensations. GFR is an important predictor of outcomes in patients with HFpEF, with decreasing estimated GFR predicting increased event rates. Finally, anemia is common in HFpEF and is associated with a worse prognosis.

Pharmacologic and Device-Based Strategies

Prospective RCTs have evaluated the efficacy of digitalis, ACE inhibitors, ARBs, and beta blocking agents in patients with HFpEF; each of these studies found no clear benefit to these therapies. An important point in this context is that these studies enrolled patients with relatively well-controlled hypertension. Therefore the results of the RCTs should not be interpreted to mean that ACE inhibitors, ARBs, and beta blocking agents do not have an important role in controlling systolic hypertension in patients with or at risk for HFpEF. In fact, a large observational study found a mortality benefit associated with the use of ACE inhibitors and ARBs in patients hospitalized with HFpEF, many of whom had uncontrolled hypertension.⁹⁷ RAAS antagonism is thus an important component of treatment in patients with HFpEF, particularly to manage hypertension, prevent or reverse LV hypertrophy, and preserve renal function in patients with diabetes.

A number of novel device-based management strategies are being developed that hold great promise for the treatment of HFpEF. These include remote monitoring systems to help tailor management and systems that modulate neurohormonal activation. Remote monitoring systems include both implantable hemodynamic monitors, noninvasive monitors (to assess measures of volume status, heart rate, rhythm, sympathetic tone, and activity) and biomarkers. Neurohormonal modulation systems include those based on renal artery denervation and vagal, carotid baroreceptor, and spinal stimulation.

Remote Monitoring Systems to Help Tailor Management

In the Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure (Compass-HF) trial, 70 patients with HFpEF (with EF >50%) were studied using an implantable hemodynamic monitor (IHM) that measured an estimated pulmonary artery diastolic pressure (ePAD), a measurement that in the absence of pulmonary vascular disease approximates PCWP. This study demonstrated that (1) patients with HFpEF demonstrated significantly increased filling pressures even while they were considered to be in a compensated state by their physicians; (2) these pressures rose further when they became decompensated; and (3) both baseline pressures and change from baseline pressures predicted outcomes.⁹⁸⁻¹⁰⁰ The investigators hypothesized that modifying treatment based on data obtained from remote monitoring using an IHM would decrease baseline pressure, prevent an increase in pressure and lower heart failure events in HFpEF. This hypothesis was tested in the CardioMEMS Heart Sensor Allows Monitoring of

Pressure to Improve Outcomes in NYHA class III Heart Failure Patients (CHAMPION) trial. One half of the 152 enrolled patients with HFpEF were managed using pulmonary artery diastolic pressure information from an IHM; the other half received standard medical therapy without knowledge of the IHM data. Those in the active treatment arm demonstrated a 152% decrease in pulmonary artery diastolic and systolic pressures and a 52% decrease in heart failure-related events (both $P < .0001$ and control). This hypothesis is undergoing further examination in the Left Atrial Pressure Monitoring to Optimize Heart Failure Therapy (LAPTOP-HF) trial, using IHM to measure left atrial pressure, that also incorporates the concept of physician-directed patient self-management. In addition to IHM systems, noninvasive systems measuring indices of impedance, heart rate variability, rhythm, and activity, are being developed and tested. Finally, repeated measurements of biomarkers, both office- and home-based, are being evaluated. These include use of BNP (HABIT-I and -II study) and galectin (REGAL-HF study).¹⁰¹⁻¹⁰⁴

Neurohormonal Modulation

Aggressive and effective management of hypertension is an essential component of treatment in HFpEF. However, many patients with HFpEF do not have adequate blood pressure control, and some have drug-refractory hypertension. Complete management of HFpEF includes the prevention of the development of LV hypertrophy or the induction of its regression. This structural remodeling and the associated abnormalities in diastolic function portend an increased risk of both mortal and morbid events.^{13,105} Treatment that results in the regression of LV hypertrophy is associated with a reduction in these event rates.^{2,8,9,74} However, success in reversing LV hypertrophy using existing pharmaceutical regimens has been neither uniform nor complete, particularly in patients with drug-resistant, refractory hypertension. Abnormalities in the autonomic nervous system appear to contribute to the resistance both to treatment and to the induction of structural remodeling.⁷⁵ The role played by autonomic imbalance in patients with HFpEF serves to underscore the importance of the development of a series of novel management strategies that target autonomic modulation.^{106,107} Initial studies in patients with refractory hypertension (a proportion of whom have HFpEF) treated with renal artery denervation (RAD) or using implanted devices for baroreceptor activation therapy (BAT), or vagal stimulation have shown that these strategies reduce blood pressure and cause regression of LV hypertrophy and improvement in diastolic function. The mechanisms responsible for these effects include both reduced LV afterload and the change in autonomic modulation itself. BAT and other autonomic modulation strategies hold significant promise for the treatment of patients with hypertensive heart disease, including those with HFpEF.

FUTURE PERSPECTIVES

Evidence-based guidelines for the treatment of symptomatic patients with HFrEF include the use of multiple drugs and devices. Thus patients with HFrEF (EF <30%) and NYHA class III status may be receiving a beta blocking agent, ACE inhibitor or ARB, aldosterone antagonist, digitalis, diuretics, CRT, and implantable cardioverter-defibrillator (ICD) treatment. Each of these treatments targets a number of different underlying pathophysiologic mechanisms that have been demonstrated to be operative in the development or progression of HFrEF. To date, when beta blocking agent, ACE inhibitor, ARB, and digitalis treatments have been applied in HFpEF, outcomes have not been successful. These facts should inform the development of novel and effective management strategies for HFpEF in the following manner. First, the difference in outcomes of RCTs using the same agents in HFrEF versus HFpEF provides evidence of important and fundamental differences between these two heart failure syndromes. These differences include distinct underlying pathophysiologic targets for treatment. Novel and effective management of HFpEF must target these pathophysiologic mechanisms including treatments that alter LV, myocardial, cellular/extracellular, and molecular structure and function. For example, treatments that restore calcium

homeostasis, change the phosphorylation state of titin, reduce ECM fibrosis, and normalize natriuretic peptide levels may each contribute to improved outcomes in HFpEF. Second, comprehensive treatment will require multiple drugs and devices that individually target multiple independent mechanisms. This multitargeted approach is necessary because each mechanism, independent of other mechanisms, probably contributes to disease progression. Therefore, like HFrEF, which often requires five drugs and two devices for effective treatment, HFpEF will require a similar multi-targeted approach whose components act synergistically to reduce morbidity and mortality in HFpEF.

GUIDELINES

Heart Failure with a Preserved Ejection Fraction

Michael R. Zile and William C. Little

No treatment has been demonstrated to reduce morbidity or mortality in patients with heart failure and a preserved ejection fraction (HFpEF). Therefore recommendations for management of patients with HFpEF are based on expert consensus as described in the 2013 American Heart Association/American College of Cardiology (AHA/

ACC) heart failure guidelines (Table 27G-1). The practical clinical management of HFpEF includes three components. First, reduce and prevent pulmonary and peripheral venous congestion. This can be accomplished with fluid and sodium restriction, judicious use of diuretics and nitrates, selective application of neurohormonal modulation, and appropriate remote monitoring based tailored care. Second, aggressive treatment of antecedent and comorbid diseases. These include controlling blood pressure both at rest and modifying blood pressure response to exercise, controlling diabetes, treating and preventing ischemia, and maintaining adequate renal function. Third, prevent excessive tachycardia or bradycardia, match heart rate to metabolic needs, maintain or restore sinus rhythm and control ventricular response rate during atrial arrhythmias.

TABLE 27G-1 ACC/AHA/HFSA/ESC Guidelines for Treatment of Patients with Stage C Heart Failure and Preserved Left Ventricular Ejection Fraction (HFpEF)

CLASS	INDICATION	LEVEL OF EVIDENCE
I (indicated)	Systolic and diastolic blood pressure should be controlled in accordance with published clinical practice guidelines to prevent morbidity. Diuretics should be used for relief of symptoms due to volume overload.	B C
Ila (good supportive evidence)	Coronary revascularization is reasonable in patients with coronary artery disease in whom symptoms (angina) or demonstrable myocardial ischemia is judged to be having an adverse effect on symptomatic heart failure. Management of atrial fibrillation according to published clinical practice guidelines is reasonable to improve symptomatic heart failure. The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure.	C C C
Ilb (weak supportive evidence)	The use of ARBs might be considered to decrease hospitalizations.	B
III (no benefit)	Routine use of nutritional supplements is not recommended.	C

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; ESC = European Society of Cardiology; HFSA = Heart Failure Society of America. See Guidelines text for definition of class and level of evidence categories.

In the current era of management of heart failure associated with a depressed left ventricular ejection fraction (LVEF), clinicians frequently encounter optimally treated patients who remain symptomatic. Indeed, despite the variety of available medical therapies and electrophysiologic interventions, such as placement of biventricular pacemakers and implantable cardioverter-defibrillators (see Chapter 26), many patients who have been so treated are still left with a reduced quality of life and a poor prognosis. In a subpopulation of these patients, surgical intervention may be appropriate to alleviate ischemia, to attenuate valvular dysfunction, to reduce mechanical disadvantages caused by ventricular remodeling, or, when all other treatment options have failed, to perform cardiac transplantation or implantation of a permanent ventricular assist device (VAD) (see Chapter 29).¹ This chapter describes the surgical management of patients with heart failure secondary to a low ejection fraction. The medical management of patients with a reduced ejection fraction is discussed in Chapter 25, and the role of circulatory assist devices is discussed in Chapter 29.

CORONARY ARTERY REVASCULARIZATION

Ischemic Cardiomyopathy

The term *ischemic cardiomyopathy* is used to describe the myocardial dysfunction that arises secondary to occlusive or obstructive coronary artery disease (see Chapter 54). Although ischemic cardiomyopathy was considered the second most common cause (after hypertension) of heart failure in the Framingham Study (see Chapter 25), ischemic cardiomyopathy is now recognized as the most common cause of heart failure in clinical trials of patients with low LVEF. This section focuses on the impact and outcome of surgical coronary artery revascularization in patients with ischemic cardiomyopathy.

Ischemic cardiomyopathy can be envisioned as three interrelated pathophysiologic processes: *myocardial hibernation*, defined as persistent contractile dysfunction at rest, caused by reduced coronary blood flow that can be partially or completely restored to normal by myocardial revascularization; *myocardial stunning*, wherein the viable myocardium may demonstrate prolonged but reversible postischemic contractile dysfunction caused by the generation of oxygen-derived free radicals on reperfusion and by a loss of sensitivity of contractile filaments to calcium; and irreversible *myocyte cell death*, leading to ventricular remodeling and contractile dysfunction.

Selection of Patients for Coronary Artery Revascularization

Until the design, completion, and publication of the STICH (Surgical Treatment of Ischemic Heart Failure) trial,² no randomized clinical

trials had evaluated the outcomes of revascularization in patients with ischemic cardiomyopathy. The three major randomized clinical trials that have compared coronary artery bypass grafting (CABG) with medical management—the Veterans Administration Cooperative Study, the European Coronary Surgery Study, and the Coronary Artery Surgery Study—all had excluded patients with heart failure or severe left ventricular (LV) dysfunction. Several clinical factors have traditionally played a major role in the decision-making process with respect to selection of suitable candidate patients with heart failure to undergo coronary artery revascularization, including the presence of angina, severity of heart failure symptoms, LV dimensions, degree of hemodynamic compromise, and presence and severity of comorbid conditions. Other major technical issues to be considered are the adequacy of target vessels for revascularization and an adequate conduit strategy. The most important determinant remains the extent of jeopardized but still viable myocardium (see Chapters 14, 16, and 17). Studies have suggested that for a significant reduction in heart failure symptoms and improvement in LV function, as well as in survival after coronary revascularization, at least 25% of the myocardium should be viable. Of interest, in the STICH trial (see further on), the presence of viable myocardium was associated with a greater likelihood of survival in patients with coronary artery disease and LV dysfunction, irrespective of treatment. The assessment of myocardial viability, however, did not identify patients with a differential survival benefit with CABG as versus medical therapy alone. The role of viability testing in the decision-making process is still evolving after the publication of this STICH trial substudy.³

Risks of Coronary Artery Bypass Grafting

The perioperative risks in patients with severe LV dysfunction range from 2% to nearly 10%, depending on the availability of targets and their viability, right ventricular dysfunction, advanced heart failure symptoms (New York Heart Association [NYHA] class IV), increased LV end-diastolic pressure, comorbidities of advanced age, peripheral vascular disease, and chronic obstructive pulmonary disease.^{4,5} The Society of Thoracic Surgeons (STS)—predicted risk of death in 2006 for a 70-year-old patient with no comorbid conditions but with a 20% LVEF was 1.6%; for a man of the same age with a normal LVEF, this risk was 0.9%. Mortality rates increase substantially when the LVEF is below 20% or when heart failure is severe (NYHA class IV).

Studies have indicated that for patients with clinical heart failure, perioperative mortality rates range from approximately 2.6% to 8.7%, depending on age and presence of one or more comorbid conditions. Pocar and associates⁵ found a 30-day mortality rate of 4.4% in 45 consecutive angina-free patients with NYHA class III or IV, LVEF

below 35%, and significant viability by positron emission tomography (PET). Predictors of death included LV end-diastolic pressure above 25 mm Hg, age older than 70 years, and significant peripheral vascular disease. In the CABG Patch trial, patients without angina or heart failure had a perioperative mortality of 1.3%. The mortality increased to 4.8% for patients with no angina and mild heart failure, NYHA class I or II, and 7.4% with no angina and NYHA class III or IV heart failure.⁵ For cardiogenic shock after myocardial infarction, the results of emergent CABG are poor but still better than medical therapy. The SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) trial gave 30-day and 6-month mortality rates after CABG of 47% and 50%, respectively, for patients in cardiogenic shock. These rates were 56% and 63% with medical therapy alone.⁶

The STICH trial was a prospective, randomized, intention-to-treat study of 2800 patients from 100 centers.² Patients on an optimal medical regimen with LV dysfunction and coronary artery disease amenable to CABG were randomly assigned to one of three different treatment strategies: CABG, CABG plus surgical ventricular reconstruction (SVR), or medical therapy alone (MED) (Fig. 28-1). This trial was powered to address two primary hypotheses: (1) CABG combined with medical therapy improves long-term survival over that achieved with MED; and (2) SVR provides additional long-term survival benefit when it is combined with CABG and medical therapy. Between July 2002 and May 2007, a total of 1212 patients with an LVEF of 35% or less and coronary artery disease amenable to CABG were randomly assigned to receive medical therapy alone (602 patients) or medical therapy plus CABG (610 patients). The primary outcome was the rate of death from any cause. Major secondary outcomes included the rates of death from cardiovascular causes and of death from any cause or hospitalization for cardiovascular causes. Of the 610 patients randomly assigned to CABG, 555 (91%) underwent CABG before the end of the study. A concurrent mitral valve operation was performed in 63 patients (11%). The all-cause death rate within 30 days of assignment to treatment, which is a rough estimation of perioperative mortality, was 4% in the medical treatment plus CABG arm, compared with 1% 30-day mortality rate in the medical treatment group (Fig. 28-2).

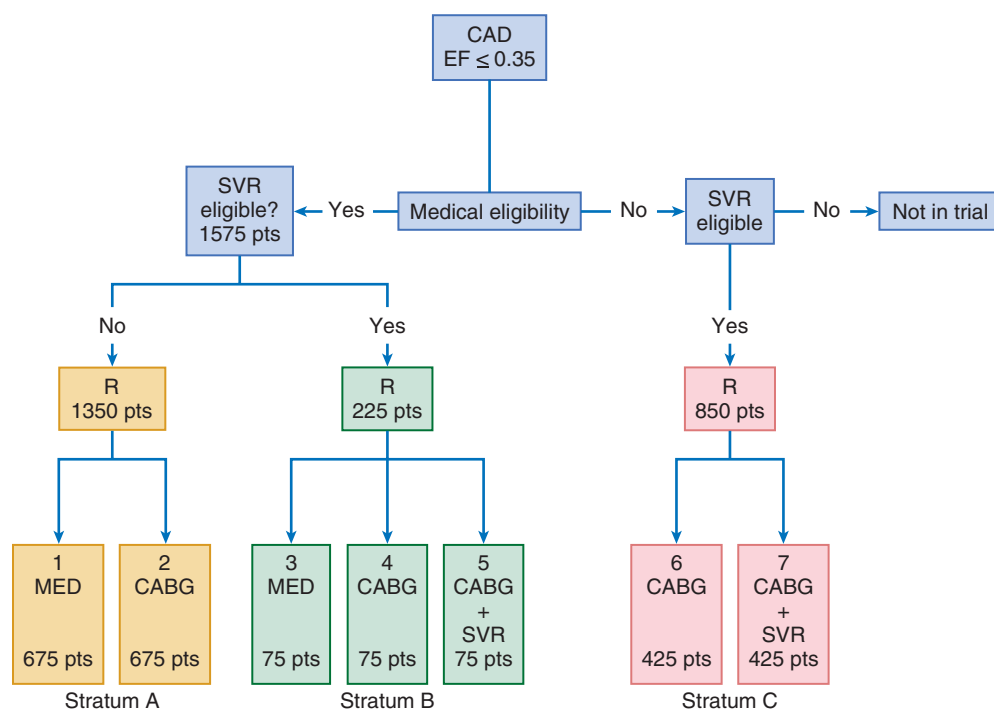

FIGURE 28-1 Treatment strata in the STICH trial. CAD = coronary artery disease; EF = ejection fraction; MED = medical therapy; R = randomized; SVR = surgical ventricular reconstruction.

Benefits of Coronary Artery Bypass Grafting

The beneficial effect of revascularization should, theoretically, result from improved blood flow to hypoperfused but viable myocardium, with a subsequent improvement in LV function and clinical outcomes. Alleviation of ischemia also may lessen the tendency toward proarrhythmias, thereby reducing the incidence of sudden cardiac death. Accordingly, coronary artery revascularization has the potential to relieve symptoms of heart failure, improve LV function, and enhance survival.

In the STICH trial, the intention-to-treat analysis (see Fig. 28-2) found no statistically significant difference in death from any cause between the medical (MED) and the surgical groups (hazard ratio [HR] for CABG, 0.86; 95% CI, 0.7 to 1.04; $P = .12$), whereas the pre-specified secondary analysis (Table 28-1) found a significant difference between the medical and surgical groups with respect to the combined endpoints of cardiovascular death, death from any cause, and hospitalization for cardiovascular causes (HR for CABG, 0.74 [95% CI, 0.64 to 0.85]; $P < .001$). The HR for cardiovascular death was 19% lower in the CABG arm (HR, 0.81; 95% CI, 0.66 to 1.00) and for the composite of death or cardiovascular hospitalization was 16% lower in the CABG arm (HR, 0.84; 95% CI, 0.71 to 0.98). These findings were consistent across several prespecified subgroups. Although the STICH trial showed no significant difference between medical therapy alone and medical therapy plus CABG with respect to all-cause death, 17% of the patients in the MED group crossed over from that arm of the study to undergo CABG. Of note, patients in the surgical (CABG) group had lower rates of death from cardiovascular causes and death from any cause or rates of hospitalization for cardiovascular causes, when compared with those patients assigned to medical therapy alone. Subsequently, Velasquez and colleagues prospectively applied the STICH trial entry criteria to an observational database to determine whether CABG decreases mortality compared with MED for patients with coronary artery disease and depressed LVEF.⁷ In their analysis, 763 patients were included for propensity score analysis, including 624 who received MED and 139 who underwent CABG. Adjusted mortality curves were constructed for those patients in the three quintiles most likely to receive CABG. The curves diverged early, with risk-adjusted mortality rates at 5 years of 46% for MED

and 29% for CABG, and the survival benefit of CABG over MED continued through 10 years of follow-up (HR, 0.63; 95% CI, 0.45 to 0.88). The investigators concluded that in a propensity-matched, risk-adjusted observational cohort of patients with coronary artery disease, LVEF less than 35%, and no left main artery stenosis greater than 50%, CABG is associated with a survival advantage over MED through 10 years of follow-up.

Improvement in Left Ventricular Function

Before publication of the STICH viability study, a review of pooled viability data demonstrated that significant viability (25% to 30%) predicted an improvement in LVEF. Nuclear studies, PET, and dobutamine echocardiography predict improvement of LV function of approximately 8% to 10% after CABG when viability of the myocardium is present. Similarly, PET, nuclear studies, or dobutamine echocardiography images that demonstrate the absence of viability are likewise

TABLE 28-1 The STICH Study Outcomes

OUTCOME	NO. OF SUBJECTS (%)		HAZARD RATIO WITH CABG (95% CI)	P VALUE
	Medical Therapy (N = 602)	CABG (N = 610)		
Primary Outcome				
Death from any cause	244 (41)	218 (36)	0.86 (0.72-1.04)	.12
Secondary Outcomes				
Death from any cause within 30 days after inclusion in study				
Logistic-regression model	7 (1)	22 (4)	3.19 (1.35-7.52) [†]	.008
Cox proportional-hazards model	7 (1)	22 (4)	3.12 (1.33-7.31)	.006
Death from cardiovascular causes	201 (33)	168 (28)	0.81 (0.66-1.00)	.05
Death from any cause or hospitalization for heart failure	324 (54)	290 (48)	0.84 (0.71-0.98)	.03
Death from any cause or hospitalization for cardiovascular causes	411 (68)	351 (58)	0.74 (0.64-0.85)	<.001
Death from any cause or hospitalization for any cause	442 (73)	399 (65)	0.81 (0.71-0.93)	.003
Death from any cause or revascularization with the use of PCI or CABG	333 (55)	237 (39)	0.60 (0.51-0.71)	<.001

*All P values were calculated with the use of the log rank test, except for one of the analyses of death from any cause within 30 days after randomization, for which, as noted, the P value was calculated with the use of the logistic regression model.

[†]This value is an odds ratio rather than a hazard ratio.

PCI = percutaneous coronary intervention.

From Velazquez EJ, Lee KL, Deja MA, et al: Coronary-artery bypass surgery in patients with left ventricular dysfunction. *N Engl J Med* 364:1607, 2011.

FIGURE 28-2 Kaplan-Meier curves for the probability of death from any cause in the STICH trial. (From Velazquez EJ, Lee KL, Deja MA, et al: Coronary-artery bypass surgery in patients with left ventricular dysfunction. *N Engl J Med* 364:1607, 2011.)

useful to predict the absence of improvement in LVEF after surgery.^{8,9} In the STICH trial, among the 1212 patients enrolled in the randomized trial, 601 underwent assessment of myocardial viability.³ Of these patients, 298 patients were randomly assigned to receive medical therapy plus CABG and 303 to receive medical therapy alone. A total of 178 of 487 patients with viable myocardium (37%) and 58 of 114 patients without viable myocardium (51%) died (HR for death among patients with viable myocardium, 0.64; 95% CI, 0.48 to 0.86; $P = .003$). The presence of viable myocardium was associated with a greater likelihood of survival in patients with coronary artery disease and LV dysfunction, but this relationship was not significant after adjustment for other baseline variables. In addition, as mentioned earlier, no significant interaction was found between viability status and treatment assignment with respect to mortality ($P = .53$), depicted in **Figure 28-3**. Although the precise reasons for the discrepancy

between results of the STICH viability study and previous studies that showed the importance of viability in predicting CABG outcomes is not known, it may relate to the more aggressive use of medical therapy in the STICH trial, which resulted in a decrease in annual mortality when compared with the mortality rates that were published in prior viability analyses. The impact of CABG on LVEF in the STICH trial has not been published.

Symptomatic Improvement

Several studies have reported marked reduction in heart failure symptoms after revascularization. In 1999, a study from Verona¹⁰ followed 167 patients, with an average LVEF of 28%, with angina and heart failure symptoms, and demonstrated significant freedom from angina after surgery, 98% and 81% at 1 and 5 years. Rates of freedom from heart failure were 78% and 47% at 1 and 5 years, respectively. Only 54% of patients were symptom-free of both angina and heart failure at follow-up evaluation. Di Carli and colleagues studied 36 patients with LVEF of 28% by PET imaging.¹¹ They found a significant correlation between the total extent of a PET blood flow-metabolism mismatch and percentage improvement in functional class after CABG. A mismatch of more than 18% was associated with a sensitivity of 76% and a specificity of 78% for predicting a change in functional status after revascularization. A substantial objective improvement in physical activity was noted in patients with presurgical mismatches that occupied at least 20% of the ventricular myocardium. Thus patients with large perfusion-metabolism mismatch exhibited the greatest clinical benefit after revascularization. The impact of the CABG strategy on subsequent symptoms of patients in the STICH trial has not been published.

A reasonable management strategy for patients who present with heart failure secondary to coronary artery disease (i.e., ischemic cardiomyopathy) includes coronary angiography (see **Chapter 20**), especially if patients have any component of angina pectoris. Viability studies may be appropriate for those patients with severe disease and adequate surgical targets. If significant viability ($\geq 25\%$) is documented, the weight of currently available clinical evidence suggests that CABG may be superior to medical therapy alone in outcome measures of survival and quality of life.⁹ Current American and European guidelines for CABG in patients with heart failure and low LVEF embody various strengths of recommendation for surgery, as shown in **Table 28-2**.¹²⁻¹⁴

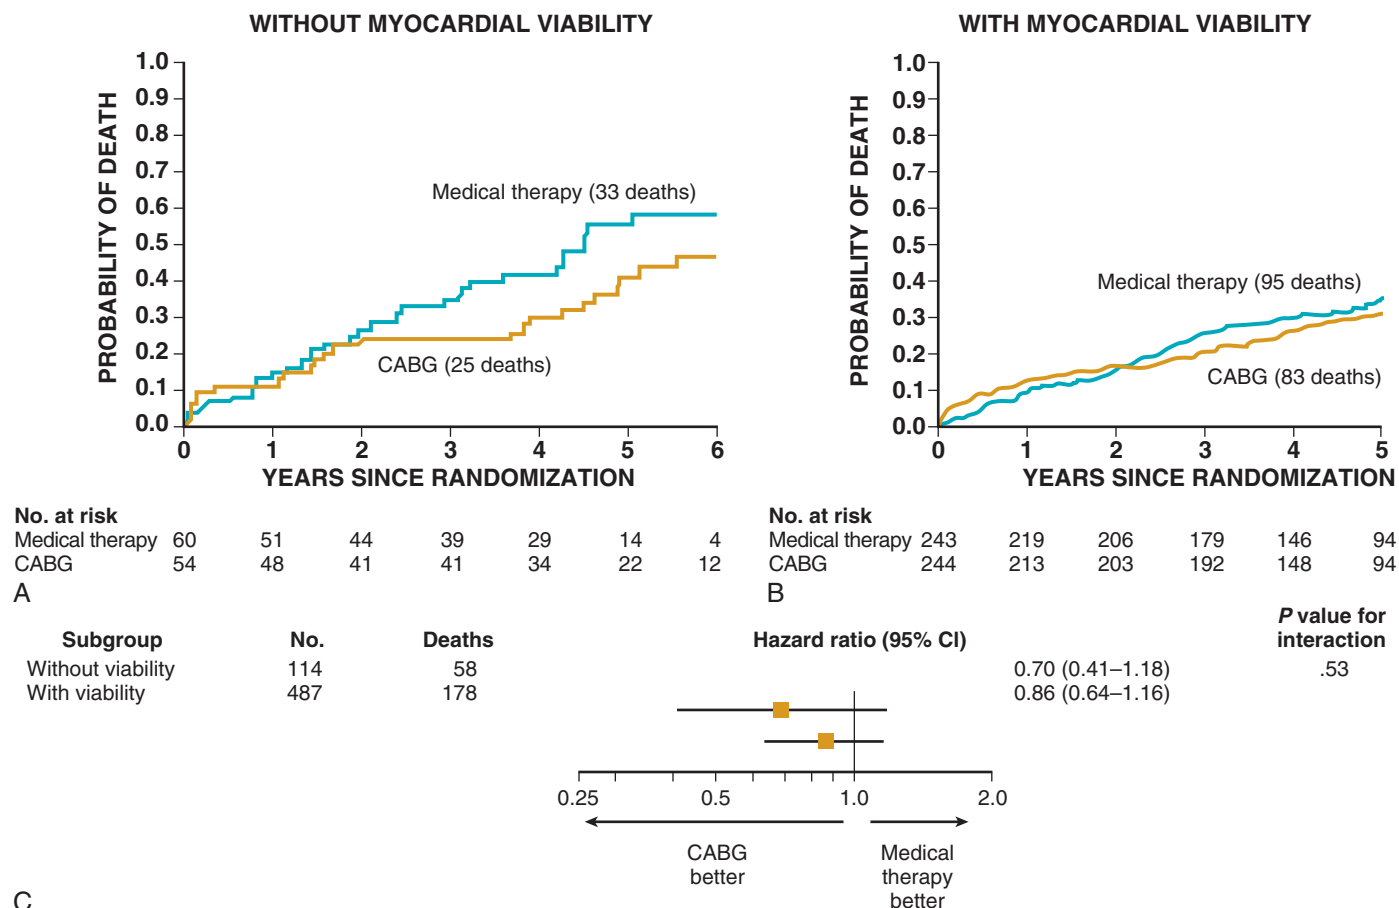

FIGURE 28-3 Kaplan-Meier analysis of the probability of death according to myocardial viability status and treatment in the STICH trial. **A**, At 5 years in the intention-to-treat analysis, the rates of death for patients without myocardial viability were 41.5% in the group assigned to undergo coronary artery bypass grafting (CABG) and 55.8% in the group assigned to receive medical therapy. **B**, Among patients with myocardial viability, the respective rates were 31.2% and 35.4%. **C**, No significant interaction was found between viability status and treatment assignment with respect to mortality ($P = .53$). VALVE SURGERY IN PATIENTS WITH LEFT VENTRICULAR DYSFUNCTION

Mitral Valve

As discussed in [Chapter 63](#), the surgical treatment of primary valvular heart disease that leads to LV dysfunction or heart failure is now widely accepted. However, patients who have valvular dysfunction secondary to, or in association with, a primary cardiomyopathy pose a much more difficult management problem. The following discussion focuses on the impact and outcome of valve repair or replacement for patients with a dilated cardiomyopathy and secondary mitral regurgitation (MR).¹⁵ However, much of the same controversy relates to the decision to repair or replace the regurgitant mitral valve in the patient with an ischemic cardiomyopathy and a low LVEF who is undergoing CABG.

MR is commonly observed in patients with heart failure and is associated with a poor prognosis. Progressive LV remodeling, characterized by increasing LV dilation with change to a more spherical shape, can result in functional MR secondary to annular dilation, papillary muscle displacement, and chordal tethering. The functional MR leads to an increased preload, increased wall tension, and increased LV workload, all of which contribute in a positive feedback loop to progressive heart failure. The presence of MR itself is an independent risk factor for poor outcome, in both nonischemic and ischemic forms of the disorder. Even uncorrected mild MR, as well as moderate to severe MR associated with ischemic cardiomyopathy, is associated with reduced long-term survival. In addition, MR is a

progressive disorder in which the regurgitation-related LV volume overload promotes further LV remodeling, leading to worsening of the problem.

Mitral valve repair or replacement to restore valve competency is a well-established procedure when symptoms of heart failure are present and the primary disease is of the valve leaflets ([see Chapter 63](#)). More specifically, however, interest has focused on functional or secondary mitral insufficiency, in which the valve leaflets are anatomically normal but do not fully coapt because of annular dilation and restricted leaflet motion secondary to increased ventricular size and sphericity. Such remodeling of the ventricle often is associated with an LVEF of 40% or less and heart failure symptoms of NYHA class III or class IV. Surgery in this situation is controversial, because the MR is the consequence and not the cause of LV dysfunction, and the prognosis is therefore more specifically related to the underlying cardiomyopathic process.

Although it is clear that the advent of secondary mitral insufficiency is associated with a worse prognosis, it is unclear whether the worse outcomes stem from the MR itself or whether MR is simply a marker for worsening heart failure and the correction of MR will improve symptoms or survival. Specifically, can surgery be done in patients with advanced heart failure and LV dysfunction with an acceptable operative mortality? Does the available evidence show that the elimination of MR results in LV reverse remodeling or improved survival? Conventional teaching has been that surgical correction of MR in patients with advanced heart failure patients with poor LV function is associated with prohibitive operative mortality.

TABLE 28-2 Surgery for Management of Heart Failure (HF): Guideline Recommendations

ESC Guidelines for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012¹²
Recommendations for Myocardial Revascularization in Patients with Chronic HF and Systolic LV Dysfunction
<ul style="list-style-type: none"> CABG is recommended for patients with angina and significant LM stenosis, who are otherwise suitable for surgery and expected to survive >1 year with good functional status, to reduce the risk of premature death; <i>class I, level of evidence: C</i> CABG is recommended for patients with angina and two- or three-vessel coronary disease, including an LAD stenosis, who are otherwise suitable candidates for surgery and are expected to survive >1 year with good functional status, to reduce the risk of hospitalization for cardiovascular causes and the risk of premature death from cardiovascular causes; <i>class I, level of evidence: B</i>
ESC/EACTS Guidelines on Myocardial Revascularization 2010¹³
Recommendations for Patients with Chronic HF and Systolic LV Dysfunction (LVEF ≤35%), Presenting Predominantly with Anginal Symptoms
<ul style="list-style-type: none"> CABG is recommended for: significant LM stenosis, LM equivalent (proximal stenosis of both LAD and LCx), proximal LAD stenosis with two- or three-vessel disease; <i>class I, level of evidence: B</i> CABG with SVR may be considered in patients with LVESV index >60 mL/m² and scarred LAD territory; <i>class IIb, level of evidence: B</i>
2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft Surgery⁴
CABG to Improve Survival Compared with Medical Therapy
<ul style="list-style-type: none"> LVEF 35% to 50%; <i>class IIa, level of evidence: B</i> LVEF <35% without significant left main CAD; <i>class IIb, level of evidence: B</i>
CABG to Improve Survival
<ul style="list-style-type: none"> CABG is reasonable in patients with mild moderate LV systolic dysfunction (LVEF 35% to 50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal LAD stenosis, when viable myocardium is present in the region of intended revascularization; <i>class IIa, level of evidence: B</i>
ESC/EACTS Guidelines on the Management of Valvular Heart Disease (Version 2012)¹⁴
Indications for Mitral Valve Surgery in Chronic Secondary Mitral Regurgitation
<ul style="list-style-type: none"> Surgery is indicated in patients with severe MR undergoing CABG and LVEF >30%; <i>class I, level of evidence: C</i> Surgery should be considered in patients with moderate MR undergoing CABG; <i>class IIa, level of evidence: C</i> Surgery should be considered in symptomatic patients with severe MR, LVEF <30%, option for revascularization, and evidence of viability; <i>class IIa, level of evidence: C</i> Surgery may be considered in patients with severe MR, LVEF >30%, who remain symptomatic despite optimal medical management (including CRT if indicated) and have low comorbidity, when revascularization is not indicated; <i>class IIb, level of evidence: C</i>

Modified from McMurray JJ, Adamopoulos S, Anker SD, et al: ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure 2012: The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012 of the European Society of Cardiology. Developed in collaboration with the Heart Failure Association (HFA) of the ESC. *Eur Heart J* 33:1787, 2012.

This view was challenged by Bolling in the mid-1990s, ushering in the era of both mitral valve repair and other surgical procedures for the failing heart.¹⁶ The traditional hypothesis held that the mitral valve functions as a “pop-off” mechanism for the failing ventricle and that surgical correction results in prohibitive mortality. The Bolling hypothesis is that there is an “annular solution for a ventricular problem . . . such that reconstruction of the mitral valve annulus’ geometric abnormality by an undersized ring restores valvular competency, alleviates excessive ventricular workload, improves ventricular geometry and improves ventricular function.”¹⁷ Miller and his Stanford colleagues reported that in an ischemic sheep model of MR, reduction of the annulus by a small ring reduces a radius of curvature of the left ventricle at the base equatorial and apical levels.¹⁸ This finding supports the concept that a small ring can restore a more elliptical ventricular shape. It is now recognized that the surgical mortality for mitral valve replacement observed in the past probably was the result of the loss of the subvalvular apparatus and not secondary to the loss of the pop-off valve as previously thought, underscoring the paramount importance of maintaining annular and subvalvular continuity during mitral valve surgery. Bolling was the first to show an acceptable operative mortality (5%) in a series of 140 NYHA class III and class IV patients with an LVEF of less than 25% and nonischemic cardiomyopathy. He demonstrated improvement in LVEF and a decrease in end-diastolic volumes during 3 to 5 years, as well as improvement in functional class.

A more comprehensive analysis of correction of MR in advanced heart failure patients with nonischemic LV dysfunction comes from Acker and colleagues in the Acorn trial.¹⁹ This trial evaluated the safety and efficacy of mitral valve surgery with and without the CorCap cardiac support device. The Acorn clinical trial, although not randomized to study the efficacy of mitral valve repair, did

prospectively assess the safety and efficacy of mitral valve surgery in patients with advanced heart failure in multiple trial centers. Of 193 subjects entered, 73% were in class III. Most of the patients had idiopathic or valvular disease; only 6% had ischemic cardiomyopathy. The mean duration of heart failure approached 5 years; 97% of patients were taking angiotensin-converting enzyme inhibitors, and 80% were taking beta blockers. The mean LVEF was 23.9%, peak $\dot{V}O_2$ was 14 mL/kg/min, and LV end-diastolic dimension was nearly 70 mm. The operative mortality rate was only 1.6%—especially noteworthy because it represents the outcomes for nearly 30 different centers. Twelve-month cumulative survival was 86.5%; at 2 years, the cumulative survival was 85.2%. A majority of patients underwent a complete, small annuloplasty repair. Mitral valve insufficiency was reduced from 2.7 at baseline to 0.6 at 18 months, accompanied by evidence of reverse remodeling. A significant decrease in LV end-diastolic volume, LVESV, and LV mass was observed out to 5 years.²⁰ Finally, the baseline NYHA class of 2.8 was reduced significantly to 2.2 at 2 years. In summary, for patients with primarily nonischemic advanced heart failure and severe LV dysfunction, mitral valve surgery has been shown to be safe, with a low operative mortality rate, and associated with significant reversal of LV remodeling compared with baseline as well as improvement in NYHA functional class.

LV reverse remodeling also has been demonstrated in several studies as a result of mitral valve repair either alone or in combination with coronary artery revascularization for patients with ischemic disease. Braun and colleagues showed that the combination of mitral valve repair and CABG resulted in a significant decrease in LV end-diastolic volume up to 4 years after surgery.²¹ Fattouch and associates demonstrated, in a randomized study of CABG versus CABG and mitral valve repair, that the addition of mitral valve repair improves

postoperative NYHA functional class and ventricular remodeling, decreases pulmonary arterial pressure, and leads to a decrease in hospitalization for heart failure.²² These same studies also showed low operative mortality rates for combined mitral valve surgery and coronary artery bypass procedures in patients with significant LV dysfunction and advanced heart failure symptoms.

In the STICH trial, the decision to treat the mitral valve during CABG was left to the surgeon.²³ Of 1212 patients who were randomly assigned, 435 (36%) had minimal MR, 554 (46%) had mild MR, 181 (15%) had moderate MR, and 39 (3%) had severe MR. In the medical arm, 70 deaths (32%) occurred in patients with minimal MR, 114 (44%) in those with mild MR, and 58 (50%) in those with moderate to severe MR. In patients with moderate to severe MR, there were 29 deaths (53%) among 55 patients randomly assigned to CABG who did not receive mitral surgery (HR versus medical therapy, 1.20 [95% CI, 0.77 to 1.87]) and 21 deaths (43%) among 49 patients who received mitral surgery (HR versus medical therapy, 0.62 [95% CI, 0.35 to 1.08]). After adjustment for baseline prognostic variables, the hazard ratio for CABG with mitral surgery versus CABG alone was 0.41 95% CI, 0.22 to 0.77; $P < .006$), (Fig. 28-4). Although this was not a randomized trial between mitral valve surgery and CABG versus CABG alone, this retrospective analysis suggests a possible benefit to the concomitant surgical procedures.

In another study, 21 centers randomly assigned 75 patients to a CABG plus reduction mitral annuloplasty as a stratum in the control arm of the RESTOR-MV (Randomized Evaluation of a Surgical Treatment for Off-pump Repair of the Mitral Valve) trial, with a mean follow-up period of 24.6 months.²⁴ Entry criteria included need for revascularization, presence of severe or symptomatic moderate functional ischemic MR, an LVEF of 25% or greater, an LV end-diastolic dimension of 7.0 cm or less, and more than 30 days since acute myocardial infarction. The 30-day mortality was 4.1% (3/73, [two patients were not randomly assigned]). Average degree of MR was reduced from 2.6 ± 0.8 preoperatively to 0.3 ± 0.6 at 2 years. The rate for freedom from death or valve reoperation was $78\% \pm 5\%$ at 2 years. Significant improvement in LVEF and NYHA class, with reduction of LV end-diastolic dimension, was observed. Cox regression analyses suggested that increasing age and renal disease were associated with decreased survival.

Mitral valve repair can be accomplished with an investigational procedure involving percutaneous implantation of a clip that grasps and approximates the edges of the mitral leaflets at the origin of the regurgitant jet.²⁵ Whether such less invasive procedures will change

the management approach to patients with poor LV function and significant MR remains to be explored. A summary of recent guideline statements about surgery for MR in patients with heart failure is presented in Table 28-2.

Multiple studies suggest that the recurrent rates of MR after repair are approximately 30% to 40%. These studies generally fail to address ring selection and amount of downsizing as an important consideration for durable results in the ischemic MR population. Early failure with recurrent MR in patients with ischemic heart failure after CABG and annuloplasty ring probably was due to the use of a flexible band or ring. These results stand in sharp contrast with little recurrent MR seen up to 4 years later when a rigid ring has been downsized by two to four sizes. Spoor and colleagues found that the MR recurrence rate was 9.5% with a flexible ring versus 2.5% with a nonflexible ring in patients with a preoperative LVEF of less than 30% and no primary mitral disease.²⁶ The failure of a flexible band in ischemic MR can be explained by the fact that the intratrigonal distance is subject to dilation, for which a band does not provide protection. In addition, fixation of the septal lateral dimension is very important in preventing return of MR, and an undersized rigid ring will address that. No randomized studies have been conducted to compare mitral valve repair with medical management in patients with advanced heart failure and LV dysfunction.

In summary, the current literature suggests that functional mitral insufficiency in patients with advanced heart failure and LV dysfunction can be corrected with a low operative mortality in either ischemic or nonischemic cardiomyopathies. There are nonrandomized series that suggesting a symptomatic benefit as well as a remodeling benefit in patients who undergo mitral valve repair in idiopathic dilated cardiomyopathies and coronary revascularization with mitral valve repair in ischemic cardiomyopathies.¹⁵ There is currently no evidence that elimination of mitral insufficiency in heart failure patients conveys a survival benefit.

Aortic Valve

The indications for valve replacement in aortic stenosis and regurgitation are discussed in Chapter 63. Here, the focus is on aortic valve replacement (AVR) for patients with aortic valve disease and significant ventricular dysfunction, typically causing heart failure. Patients with aortic stenosis may develop ventricular dysfunction with a low gradient across the aortic valve (see Chapter 63). AVR is warranted in these patients if the LV dysfunction is secondary to the aortic stenosis. Accordingly, it is important to differentiate between pseudo-obstruction, with poor ventricular function leading to reduced opening of the aortic valve, and true aortic stenosis. In the latter case, a primary valve obstruction leads to LV dysfunction in patients with aortic stenosis and a low cardiac output. Dobutamine echocardiography is useful to make this determination (see Chapter 14).

Although patients with true aortic stenosis and LV dysfunction have been deemed inoperable in the past because of the concern of perioperative mortality, the prognosis for these patients, if they do not receive an AVR, is extremely poor, with 1-year, 5-year, and 10-year survival rates of 62%, 32%, and 18%, respectively.²⁷ No definitive trials have been conducted to demonstrate that concomitant pharmacotherapy has any impact on survival. Conversely, studies have indicated that this population of patients can undergo surgery safely, with better outcomes than with medical therapy alone. In a study from the Cleveland Clinic, the in-hospital mortality for this group of patients was 8%, with a 1-year survival rate of 82%, versus 41% for those treated with medical therapy alone; 4-year survival rates of 78% and 15% were noted for those treated with AVR and medical therapy alone, respectively.²⁸ Assuming that the patient has true aortic stenosis with a depressed cardiac output and a low gradient, the risk-to-benefit ratio would favor surgical interventions in those patients who are otherwise healthy enough to undergo surgery. More recently, the increasing availability of transcatheter aortic valvular replacement (TAVR), a catheter-based

(From Deja MA, Grayburn PA, Sun B, et al: Influence of mitral regurgitation repair on survival in the surgical treatment for ischemic heart failure trial. *Circulation* 125:2639, 2012.)

approach to replacement of the aortic valve, may change again the decision-making process in the management of patients with heart failure and aortic stenosis (see Chapter 63).²⁹ Currently, most patients with significant LV dysfunction are excluded from TAVR procedures, but this ruling will undoubtedly change as the technology develops. Another common clinical scenario is that in which the patient who is to undergo CABG is found to have some degree of aortic stenosis as well. Studies and guideline recommendations suggest that in many situations, a dual procedure of CABG and AVR can be safely performed with better long-term outcomes.³⁰

The management of patients with severe aortic regurgitation and LV dysfunction poses a different problem. Some patients develop advanced heart failure and have been considered for cardiac transplantation because the LV dysfunction was considered to be irreversible. Although the operative mortality in this group has been high historically, a study from the Cleveland Clinic has indicated that for patients with pure aortic regurgitation, the operative mortality has been negligible since 1985.³¹ In this series, regression in LV mass and improvement in LV volumes were observed in most patients after aortic valve replacement surgery. A more recent study has suggested that left ventricular mass regression after AVR for chronic aortic regurgitation is greatest in patients with the largest preoperative indexed LV mass. Although late survival may not be as good for patients with normal preoperative LV function with severe aortic insufficiency, the outcomes may be better than with the option of cardiac transplantation or continued medical therapy. Although a number of series have examined the prognostic variables after aortic valve surgery, patients with both low LVEF and significant aortic insufficiency are included only in small numbers.^{30,32} Guidelines have encouraged the surgical management of patients with significant aortic regurgitation before the onset of significant heart failure symptoms and/or severe LV dilation for many years now. More recently, newer surgical procedures have used aortic valve repair or aortic root replacement as better procedures than AVR alone in the patient with primarily aortic regurgitation.³³

In summary, in experienced centers, mitral valve repair for patients with LV dysfunction and MR may be appropriate for those undergoing CABG as well as for selected patients with idiopathic dilated cardiomyopathy who remain symptomatic despite optimal medical therapy. Aortic valve surgery can be performed safely, albeit at higher operative risk, in patients with severe LV dysfunction and heart failure, and it appears to have a better clinical outcome than that achieved with current medical therapy in observational studies.

LEFT VENTRICULAR RECONSTRUCTION

Revascularization and valve operations lead to clinical improvement in many patients, but in others, ventricular dilation and dysfunction are so severe that direct ventricular surgery has been proposed to optimize cardiac function. Patients who have a transmural myocardial infarction may develop ventricular dilation and remodeling that lead to changes in increased LV wall stress and LV dysfunction. A host of adverse events are initiated, including increased myocardial oxygen consumption secondary to increased wall stress, increased neurohormone and cytokine levels, afterload mismatch, and subendocardial hypoperfusion. The stated goals of ventricular reconstruction are to remove or to exclude the infarcted segment to restore an elliptical ventricular chamber, to diminish remote wall stress, to promote helical fiber orientation and to increase thickening of the akinetic or dyskinetic portion of the chamber, to reduce end-systolic volume, to diminish mitral insufficiency, and to eliminate residual ischemia. Concomitant CABG often is necessary, and if more than moderate MR is present, this should be corrected separately. This type of operation is variously named surgical ventricular reconstruction (SVR) or the Dor procedure (after Vincent Dor), in which the aneurysm or akinetic segment is reconstructed, typically with a patch (endoventricular patch plasty).³⁴

The operation is performed through the area of scar. A pursestring suture is placed between the infarcted and normal myocardium. An

endoventricular Dacron patch usually is used to exclude the infarcted segment, with closure of the aneurysm sac over the patch. A mandrel often is used to ensure that adequate ventricular volume is maintained. This operation typically is reserved for patients who have had a large anterior-apical infarct that involves the apex, anterior wall, and septum with resulting LV remodeling. Ideally, the operation was designed to reduce end-systolic volumes by at least 30% while ensuring adequate size of the ventricle.

The RESTORE (Reconstructive Endoventricular Surgery returning Torsion Original Radius Elliptical shape to the left ventricle) multicenter study investigated various techniques for LV reconstruction in a registry of 1198 patients with post-anterior infarction heart failure operated on between 1998 and 2003. Concomitant procedures included CABG in 95% and mitral valve repair in 22%. The operative mortality rate in patients who underwent LV reconstruction was 5.3%. At 5 years, the overall survival rate was $68\% \pm 2.8\%$, and freedom from hospital readmission for heart failure was confirmed in 78%. Logistic regression analysis identified LVEF of less than 30%, LV end-systolic volume index 80 mL/m^2 or higher, advanced NYHA functional class, and age older than 75 years as risk factors for death. LV reconstruction resulted in a significant decrease in LV end-systolic volume index (from 80.0 ± 5.1 to $56.0 \pm 34.3 \text{ mL/m}^2$) and a significant increase in LVEF (from $29\% \pm 11.0\%$ to $39\% \pm 12.3\%$).³⁵ Clinicians worldwide embraced this reconstructive surgery, and one arm of the STICH trial further explored the usefulness of this operative procedure for patients with ischemic cardiomyopathy.

The SVR portion of the STICH trial (hypothesis 2) tested whether adding SVR to CABG in ischemic heart failure patients would decrease death from any cause or cardiac rehospitalization when compared with CABG alone.³⁶ This substudy included 1000 patients (operated on between 2002 and 2006) with heart failure who had concomitant coronary artery disease, LVEF of less than 35%, and anterior LV wall scar amenable to SVR. Bypass surgery alone was performed in 499 patients, and CABG plus SVR was performed in 501 patients. They were studied for a median follow-up period of 48 months. No significant difference was found in the primary outcome variable of death from any cause or hospitalization for cardiac causes (HR for SVR plus CABG, 0.99; 95% CI, 0.84 to 1.17; $P = .90$) during the 5 years of the study¹⁷ (Fig. 28-5).

The results of the study have been criticized because the average percentage reduction in end-systolic volume after CABG plus SVR was only 19%—below the accepted criterion for successful LV reconstruction, which requires a 30% (minimum) reduction in end-systolic volume.³⁷ In addition, the absolute end-systolic volume index in the STICH patients undergoing CABG plus SVR was 67 mL/m^2 . The results of Menicanti and colleagues demonstrated that patients who were left with a residual end-systolic volume index greater than 60 mL/m^2 had a worse survival than that achieved in those with a more optimal end-systolic volume index of less than 30 mL/m^2 .³⁸ An additional limitation of the STICH trial is that 13% of patients did not have an infarct before development of LV dysfunction. A final criticism is that with an ongoing selection bias, the study did not include patients thought to clearly benefit from SVR. Many surgeons think that because of these possible shortcomings in the trial, STICH did not prove or disprove the original hypothesis.^{38,39} Certainly, ongoing investigations are looking at predictors of success using the SVR operation in other cohorts outside of the STICH trial.

PASSIVE CARDIAC SUPPORT DEVICES

The preceding sections have outlined direct surgical reconstruction of coronary arteries, valves, or the left ventricle. Novel surgical approaches also have been undertaken to inhibit or to reverse LV remodeling, including passive cardiac support devices developed out of original observations with dynamic cardiomyoplasty, which initially was intended to act as an auxiliary pump for the failing heart. Subsequent hemodynamic assessments in animals and humans have suggested that much of the observed benefit of dynamic cardiomyoplasty appeared to be derived from the passive girdling effect of the

FIGURE 28-5 Results of STICH trial showing no benefit for SVR and CABG over CABG alone. (From Jones RH, Velazquez EF, Michler RE, et al: Coronary bypass surgery with or without surgical ventricular reconstruction. *N Engl J Med* 360:1705, 2009.)

muscle wrap, which limits ventricular dilation, reduces LV wall stress, and prevents LV remodeling. These early experiences with dynamic cardiomyoplasty and the insights into its biologic effects led to the development of surgical therapies specifically aimed at inhibiting LV remodeling. Unfortunately, the two different cardiac support devices that have undergone clinical trials (Acorn Pivotal Trial and PEERLESS-HF) either were stopped for futility (PEERLESS-HF) or failed to show a convincing risk-to-benefit profile (Acorn Pivotal Trial) despite a long-term follow-up evaluation of the patients that did not identify any safety concerns and demonstrated apparently favorable outcomes. At present, no U.S. Food and Drug Administration (FDA)-approved cardiac support devices are available in the United States.

CARDIAC TRANSPLANTATION

Donor Allocation System

In the United States, the allocation of donor organs is accomplished under the supervision of the United Network of Organ Sharing (UNOS),

a private organization under contract to the federal government. The United States is divided geographically into 11 regions for donor heart allocation. Under UNOS policy, thoracic organs are distributed on the basis of blood type, medical urgency, and time on the waiting list. The physiologic limit of approximately 4 to 5 hours of ischemic out-of-body time for hearts precludes a national sharing of donor hearts. Currently, the highest priority for patients to receive donor organs is assigned according to the severity of illness. Each candidate awaiting heart transplantation is assigned a status corresponding to the medical urgency for that candidate. For a candidate who is 18 years of age or older at the time of listing, medical urgency is assigned according to UNOS policies. Status 1A refers to patients who are hospitalized and have a left or right VAD, a total artificial heart, an extracorporeal membrane oxygenation system, a ventilator, or a balloon pump; this is valid for 30 days unless the patient is relisted. Patients have only a one-time window of 30 days after receiving an implantable VAD unless they develop device-related infection or device failure; a patient with invasive hemodynamic monitoring and two or more inotropic drugs also meets the requirement for status 1A. Status 1B refers to hospitalized patients who are being treated with a right or left VAD after their initial 30-day window as status 1A or a continuous intravenous infusion of inotropes. A candidate who does not meet the criteria for status 1A or 1B is listed as status 2; these candidates often are those outpatients who are stable on a medical regimen. A candidate who is listed as status 7 is considered temporarily unsuitable to receive a thoracic organ transplant (see also policies of the Organ Procurement and Transplantation Network [<http://optn.transplant.hrsa.gov/>]).

In the United States, as many as 40% of patients listed and waiting for a heart transplant are implanted with a VAD to maintain end-organ integrity, to reduce pulmonary vascular resistance, and to improve functional capacity. Serious debate has emerged concerning the cost of these two procedures, the outcomes for these patients compared with those for transplant recipients without a VAD during the waiting period, and the rationale for conferring an automatic higher waiting status to patients after VAD surgery as a bridge to transplantation.⁴⁰

Evaluation of the Potential Recipient

Figure 28-6 outlines the questions that must be answered to evaluate a potential patient for cardiac transplantation. Patients estimated to have less than a 1-year life expectancy are the usual candidates, because the considerable risks of the transplant procedure must be taken into account. Typically, patients for consideration have (1) cardiogenic shock requiring mechanical support or high-dose inotropic or vasopressor drugs (in which case the irreversibility of their course is usually clear); (2) chronic progressive, refractory, or stage D heart failure symptoms despite optimal therapy⁴¹; (3) recurrent life-threatening arrhythmias despite maximal interventions, including implanted defibrillators; or, rarely, (4) refractory angina without potential for revascularization.⁴² More recently, adult patients with repaired congenital heart disease are more often presenting with progressive heart failure; these patients are being increasingly considered for heart transplantation.⁴³ Several models have been proposed to assist in the risk stratification of patients with heart failure by use of both invasive and noninvasive methods.⁴⁴ Two models to assess the prediction of risk in a patient who will undergo transplantation also have been proposed, one of which is shown in **Figure 28-7**.^{45,46} The most potent predictor of outcome in ambulatory patients with heart failure has been a symptom-limited metabolic stress test to calculate peak oxygen consumption, or peak $\dot{V}O_2$. A peak $\dot{V}O_2$ of less than 12 mL/kg/min indicates a poor prognosis, with likelihood of survival less than that with transplantation.⁴⁷ The lack of applicability of $\dot{V}O_2$ in patients too sick

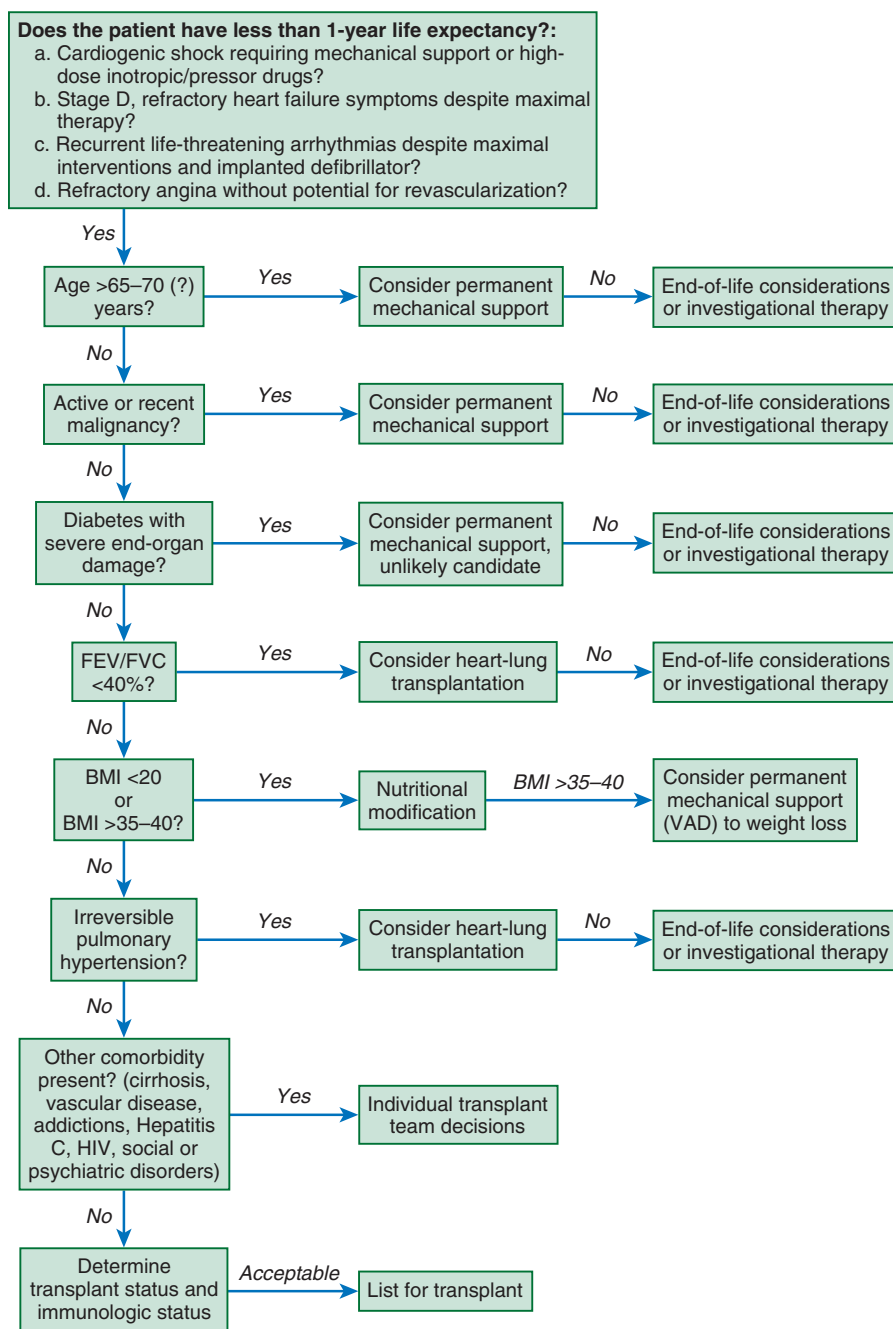

FIGURE 28-6 Evaluation of the potential heart transplant recipient. FVC = forced vital capacity; FEV = forced expiratory volume.

to exercise, however, has necessitated the use of other methods of risk assessment. Nonambulatory patients requiring continuous intravenous inotropic support who cannot be weaned or who require mechanical support to maintain adequate cardiac index are more obviously at risk for a poor outcome without transplantation, but signs and symptoms of end-organ failure of the pulmonary, hepatic, and renal systems, which may signal an ominous prognosis even with a transplant procedure, are often manifested.

Each patient must then undergo an extensive medical and psychosocial evaluation by the transplant team to exclude contraindications to transplantation, to further efforts at prognosis, to determine the urgency of transplantation, and to determine immunologic status. A number of relative contraindications to heart transplantation are recognized; one of the most debated and variable among centers is the upper age limit for consideration. In general, patients older than 70 years are ineligible and more often are assigned to high-risk reparative

surgery, permanent cardiac assist devices, or investigational therapies, such as cell transplantation, or to receive hearts from an alternate list of less-than-optimal donors. Nevertheless, some transplant centers maintain that carefully selected patients older than 70 can achieve outcomes equivalent to those obtained in younger patients.⁴⁸ An active or recent malignant neoplasm, diabetes with severe end-organ damage, and other metabolic abnormalities that may limit life expectancy after transplantation are common reasons to exclude potential recipients. Significant lung disease complicates postoperative management and precludes the possibility of normal physical functioning; extremes of weight, as measured by body mass index (BMI), also have been shown to worsen post-transplantation prognosis. Patients with advanced heart failure associated with renal dysfunction generally are excluded from heart transplantation, because abnormal renal function increases morbidity after transplantation. Alternatively, some centers have successfully performed simultaneous heart and kidney transplants in patients with advanced kidney disease, using organs from the same donor. Thus it is important to clearly distinguish patients with potentially reversible renal failure from those patients in whom renal dysfunction is associated with advanced, irreversible end-stage renal disease.

Pulmonary arterial hypertension, with a pulmonary vascular resistance of more than 6 Wood units that cannot be reduced by medical therapy or after the placement of a VAD, is considered an absolute contraindication to cardiac transplantation. In the setting of fixed pulmonary hypertension, the donor right ventricle often will fail, leading to a high rate of early postoperative mortality.⁴⁹ In patients with irreversible pulmonary pressures, some centers may consider individual patients for a combined heart-lung transplant procedure. Other comorbid conditions that may have a negative impact on a transplant team's decision to further consider a potential recipient include hepatitis C or cirrhosis, peripheral or cerebral vascular disease, advanced neuropathy, human immunodeficiency virus (HIV) status, addictions to alcohol or illicit drugs, and social or psychiatric disorders.

An increasingly sophisticated immunologic evaluation of each patient is done for ABO blood typing and antibody screening, panel-

reactive antibody (PRA) level determination, and human leukocyte antigen (HLA) typing. The PRA test can identify the presence of circulating anti-HLA antibody but not the specificity or strength of antibody. Enzyme-linked immunoassay and flow cytometry can also determine PRA level and are more sensitive than the cytotoxic test.⁵⁰ Virtual crossmatch methods, in which flow cytometry-based single-antigen bead assays allow the clear identification of antibody specificities, are now being used with some success. Prospective donors with these antigens can be avoided, and a compatible donor can be selected without the need for a prospective crossmatch.⁵¹ This approach allows an increased rate of donor matching outside the geographic area of the local organ procurement organization.

The Cardiac Donor

In light of an increasing organ demand, efficacious donor management and meticulous selection are crucial in maintaining excellent

transplant outcomes. Obviously, it is critical to obtain a complete medical history for the donor, including any relevant cardiovascular disorders before brain death. All donors are screened for communicable diseases, including viral disorders such as hepatitis and HIV infection. Specific information that is relevant for the assessment of cardiac donor suitability also includes the presence or absence of thoracic trauma, disseminated cancer, donor hemodynamic stability, pressor and inotropic requirements, duration of cardiac arrest, and need for cardiopulmonary resuscitation. In some cardiac donors, hemodynamic deterioration may be caused by brain death. Cardiac echocardiography is required on all donors, and coronary arteriography is required to evaluate the presence of coronary artery disease in donors older than 45 to 50 years, depending on other risk factors.

The acceptable cold ischemia time for cardiac transplantation is approximately 4 to 5 hours. Prolonged ischemic time has been shown to be a significant risk factor for death after cardiac transplantation, especially when it is coupled with other risk factors, such as older donor age. Donors up to the age of 60 to 65 years are currently considered, depending on transport distance and other donor risk factors. The final decision to accept a heart for transplantation is made at the time of harvesting, after direct examination of the heart for coronary calcification, as well as LV hypertrophy or dilation. A recent randomized trial has shown that treatment of brain-dead donors with dopamine of 4 $\mu\text{g/kg/min}$ will not harm cardiac allografts but appears to improve the clinical course in the heart transplant recipient.⁵²

Surgical Considerations

The two most common surgical approaches for the implantation of the donor heart are the biatrial and the bicaval anastomoses. The bicaval anastomosis technique was introduced with the intention to reduce right atrial size, to minimize distortion of the recipient heart, to preserve atrial conduction pathways, and to decrease tricuspid regurgitation. This alternative procedure entails five anastomoses: left atrium, pulmonary artery, aorta, inferior vena cava, and superior vena cava. Although no prospective trial has been conducted to

establish the superiority of either technique, the bicaval technique is now being done most often in the United States, primarily because it appears to decrease the need for permanent pacemakers in transplant recipients.⁵³ Most important, the number of patients coming to transplantation with ventricular assist devices in place has steadily increased, so that transplant procedures are riskier and result in more bleeding.⁵⁴

The most common reason for failure to wean a heart transplant recipient from cardiopulmonary bypass is right-sided heart failure, evidenced by a low cardiac output despite a rising central venous pressure. The right side of the heart can be seen in the surgical field to dilate and to contract poorly. Intraoperative transesophageal echocardiography shows a dilated, poorly contracting right ventricle and an underfilled, vigorously contracting left ventricle. Right ventricular function may be enhanced with inotropes and pulmonary vasodilators, but the prognostic importance of preoperative pulmonary vascular resistance becomes obvious in these first few hours after surgery.^{55,56}

Immunosuppression

Immunosuppressive regimens begin with the simultaneous use of three classes of drugs: glucocorticoids, calcineurin inhibitors, and antiproliferative agents. In a subset of patients, transplant teams use a variety of drugs for induction therapy to rapidly enhance immune tolerance. In the immediate postoperative period, immunosuppressive agents are given parenterally with a quick transition to oral formulations.

Corticosteroids are nonspecific antiinflammatory agents that work primarily by lymphocyte depletion. Patients initially receive high doses of intravenous and then oral corticosteroids, which are gradually tapered during the next 6 months; the goal often is to withdraw corticosteroid therapy completely. At many centers, corticosteroids are given several hours before the transplant surgery. Side effects include cushingoid appearance, hypertension, dyslipidemia, weight gain with central obesity, peptic ulcer formation and gastrointestinal bleeding, pancreatitis, personality changes, cataract formation, hyperglycemia progressing to corticosteroid diabetes, and osteoporosis with avascular necrosis of bone. The well-appreciated adverse side effect profile of the corticosteroids has led to a number of innovative strategies to eliminate them as early as possible after the transplant surgery. Corticosteroids usually are the agents of first choice to treat acute rejection as well.⁵⁷

There are two calcineurin inhibitors, cyclosporine and tacrolimus. Their main mechanism of action involves binding to specific proteins to form complexes that block the action of calcineurin, a key participant in T cell activation. The calcineurin inhibitors serve to block the signal transduction pathways responsible for T cell and B cell activation and therefore act specifically on the immune system and do not affect other rapidly proliferating cells. Critical and often limiting adverse effects include nephrotoxicity in as many as 40% to 70% of patients and hypertension with the development of LV hypertrophy; both drugs cause roughly equivalent numbers of these untoward events. Hirsutism, gingival hyperplasia, and hyperlipidemia are more frequent with cyclosporine, and diabetes and neuropathy are more frequent with tacrolimus. In addition, an increased incidence of deep vein thrombosis, tremor, headache, convulsions, and paresthesias of the limbs has been reported with both drugs.⁵⁸

Antiproliferative agents work to either directly or indirectly inhibit the expansion of alloactivated T cell and B cell clones. Azathioprine was the earlier agent used in this class and served as the mainstay of immunosuppression even before the routine use of cyclosporine. In the past decade, mycophenolate mofetil (MMF) has replaced azathioprine as the first-line antiproliferative agent, with several randomized trials demonstrating superiority compared with azathioprine.⁵⁹ MMF is hydrolyzed to mycophenolic acid, which inhibits de novo purine synthesis. Both azathioprine and MMF cause leukopenia as their major adverse effect; the use of MMF can be limited by debilitating diarrhea or nausea. It is likely that the combination of MMF and tacrolimus potentiates their individual adverse effects.

FIGURE 28-7 Kaplan-Meier cumulative 1-year survival of recipients in the derivation cohort (A) and validation cohort (B) as stratified by three-point increments of risk in the IMPACT score used to predict risk of death for patients undergoing orthotopic heart transplantation. (From Weiss ES, Allen JG, Arnaoutakis GJ, et al: Creation of a quantitative recipient risk index for mortality prediction after cardiac transplantation (IMPACT). *Ann Thorac Surg* 92:914, 2011.)

Sirolimus (often called rapamycin) and everolimus are two newer agents that block activation of T cells after autocrine stimulation by interleukin-2. They also are known to inhibit proliferation of endothelial cells and fibroblasts. Their action is complementary to that of calcineurin inhibitors, and both sirolimus and everolimus have been used as maintenance immunosuppression, as alternatives to standard immunosuppression, and as rescue drugs for rejection. Sirolimus, an m-TOR inhibitor, has been shown to slow progression of cardiac allograft vasculopathy (CAV) with established disease,⁶⁰ and everolimus has been demonstrated to reduce both acute rejection and CAV. In one randomized trial comparing sirolimus and azathioprine, with cyclosporine and corticosteroids, the sirolimus regimen decreased by half the number of patients experiencing acute rejection, which resulted in less subsequent development of CAV.⁶¹ Because the drugs inhibit the proliferation of fibroblasts, they may cause significant difficulties with wound healing, and many centers do not use them for initial therapy immediately after the transplant surgery, although several centers have reported encouraging results using sirolimus as a primary immunosuppressive agent as an alternative to a calcineurin inhibitor. The drugs also have been associated with the development of significant pericardial effusions. Sirolimus has been increasingly used to replace the calcineurin inhibitors as a strategy to improve renal dysfunction or to reverse LV hypertrophy.⁵⁸

The longstanding use of the maintenance combination of cyclosporine, azathioprine, and corticosteroids has been challenged in a number of trials. Tacrolimus plus MMF, or tacrolimus plus sirolimus, was evaluated against cyclosporine plus MMF in a multicenter trial.⁶² Overall 1-year survival did not differ among the three regimens, but statistically less significant rejection with or without hemodynamic compromise was reported in the tacrolimus plus MMF arm compared with the cyclosporine plus MMF arm. Overall, patients in the tacrolimus plus MMF group had better renal function and triglyceride levels at 1 year. This trial has been pivotal in moving tacrolimus to a role of primary calcineurin inhibitor used worldwide. The TICTAC (Tacrolimus in Combination, Tacrolimus Alone Compared) trial reported that the addition of mycophenolate to single-agent immunosuppression with tacrolimus did not provide an advantage over single-agent immunosuppression in terms of rejection, CAV, or 3-year survival.⁶³ Corticosteroids were successfully discontinued in all patients. The statistical power of the trial, which included only 150 patients, has been questioned, but these findings have led the heart transplant community to explore a strategy of even less immunosuppression in selected patients.

Rejection

Rejection involves cell- or antibody-mediated cardiac injury resulting from recognition of the cardiac allograft as non-self. By histologic and immunologic criteria, this process is categorized into three major types of rejection: hyperacute, acute, and chronic. *Hyperacute* rejection results when an abrupt loss of allograft function occurs within minutes to hours after circulation is reestablished in the donor heart and is rare in modern-day transplantation. The phenomenon is

mediated by preexisting antibodies to allogeneic antigens on the vascular endothelial cells of the donor organ, which is now avoided with current HLA typing techniques. These antibodies fix complement, which promotes intravascular thrombosis. Subsequently, rapid occlusion of graft vasculature occurs, followed by swift and overwhelming failure of the cardiac graft.

Acute cellular rejection or cell-mediated rejection is a mononuclear inflammatory response, predominantly lymphocytic, directed against the donor heart; it is most common from the first week to several years after transplantation, and it occurs in up to 40% of patients during the first year after surgery. The key event in both the initiation and the coordination of the rejection response is T cell activation, moderated by interleukin-2, a cytokine. Interleukin-2 is produced by CD4⁺ cells and to a lesser extent by CD8⁺ cells and exerts both an autocrine and a paracrine response. Unlike in renal and liver transplants, no reliable serologic markers for rejection in the cardiac transplant have been identified. Therefore the endomyocardial biopsy remains the gold standard for the diagnosis of acute rejection (see also Chapter 67). Biopsies are performed via a transjugular approach weekly and then every other week for several months; monthly biopsies continue for 6 to 12 months in many programs and for years thereafter in some. Cell-mediated rejection is graded according to a universally agreed-on system, as shown in Table 28-3.⁶⁴ Endomyocardial biopsies are invasive and painful and may cause serious adverse events such as pericardial tamponade or tricuspid insufficiency. Accordingly, efforts continue to develop a serologic assay composed of gene expression or transcriptional factors that are significantly regulated during cardiac rejection.⁶⁵ The largest trial to date, IMAGE (Invasive Monitoring Attenuation through Gene Expression), demonstrated that among selected patients who had received a cardiac transplant more than 6 months before entering the study, and who were at a low risk for rejection, a strategy of monitoring for rejection that involved gene-expression profiling, as compared with use of routine biopsies, was not associated with an increased risk of serious adverse outcomes and resulted in the performance of significantly fewer biopsies.⁶⁶ It is not clear how readily this assay has been adopted in the United States, although the study seems to have resulted in a lower rate of endomyocardial biopsies done only for protocol.

Risk factors for early rejection include younger recipient age, female sex, female donor, positive cytomegalovirus serologic test results, prior infections, black recipient race, and number of HLA mismatches. Most important, patients who fail to take or to tolerate their immunosuppressant drugs, especially early in the postoperative course, are at very high risk for severe or recurrent cellular rejection. The occurrence of one or more episodes of treated rejection during the first year is a risk factor for both failure to attain 5-year survival and development of transplant-related coronary artery disease. Likewise, treatment of acute rejection in the first 6 months after transplantation contributes to a slower overall rehabilitation of the patient.

The aggressiveness of treatment for cell-mediated rejection depends on the biopsy grade, clinical correlation, patient risk factors,

TABLE 28-3 Current Grading System for Cell-Mediated Rejection in Heart Transplantation Compared with an Earlier System

2004 SYSTEM		1990 SYSTEM	
Grade 0 R	No rejection	Grade 0	No rejection
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage	Grade 1, mild A—focal B—diffuse	Focal perivascular and/or interstitial infiltrate without myocyte damage Diffuse infiltrate without myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage	Grade 2, moderate (focal)	One focus of infiltrate with associated myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage, ± vasculitis	Grade 3, moderate A—focal B—diffuse Grade 4, severe	Multifocal infiltrate with myocyte damage Diffuse infiltrate with myocyte damage Diffuse, polymorphous infiltrate with extensive myocyte damage ± hemorrhage ± vasculitis

rejection history, length of time after transplantation, and whether or not target levels of the immunosuppressant drugs are achieved. For example, an asymptomatic, early moderate rejection occurring soon after transplantation in a patient in whom immunosuppressants are at or above target levels, or who has one or more risk factors for early rejection, would be treated more aggressively than low-risk patient with no previous history of cell-mediated rejection.

Another form of acute rejection is acute humoral rejection, or antibody-mediated rejection, which occurs days to months after transplantation and is initiated by antibodies rather than by T cells. The alloantibodies are directed against donor HLA or endothelial cell antigens. Antibody-mediated rejection is a serious complication after heart transplantation and is manifested as “graft dysfunction” or hemodynamic abnormalities in the absence of cellular rejection on biopsy. Antibody-mediated rejection is now recognized as a distinct clinical entity, and strict histopathologic and immunologic criteria for its diagnosis have been established, as shown in **Table 28-4**.⁶⁴ Patients at greatest risk for antibody-mediated rejection are women and patients with a high PRA level or a positive crossmatch. It is estimated that significant antibody-mediated rejection occurs in about 7% of patients, but the rate may be as high as 20%. Because antibody assays are becoming more precise, it is probable that more antibody-mediated rejection will be recognized, with a correlating need for newer treatment algorithms.

Chronic rejection, or late graft failure, is an irreversible gradual deterioration of graft function that occurs in many allografts months to years after transplantation. Current concepts suggest that donor heart dysfunction in the chronic stages of maintenance immunosuppression is either related to chronic rejection, mediated by antibodies, or a result of progressive graft loss from ischemia. The latter process is characterized by intimal thickening and fibrosis, leading to luminal occlusion of the graft vasculature, and is often referred to as CAV or transplant coronary artery disease.

Infection

Despite the advances in immunosuppressive management, a major untoward consequence remains the occurrence of life-threatening infections. Infections cause approximately 20% of deaths within the first year after transplantation and continue to be a common contributing factor in morbidity and mortality throughout the recipient's life. The most common infections in the first month after surgery are nosocomial bacterial and fungal infections related to mechanical ventilation, catheters, and the surgical site. Mortality is highest for fungal infections, followed by protozoal, bacterial, and viral infections. Aspergillosis and candidiasis are the most common fungal infections after heart transplantation. Viral infections, especially those due to cytomegalovirus, can enhance immunosuppression, potentially resulting in additional opportunistic infections. Accordingly, patients typically are given a prophylactic regimen against cytomegalovirus, *Pneumocystis jirovecii*, and herpes simplex virus infections and oral candidiasis, to be used during the first 6 to 12

months after transplantation. Prophylactic intravenous ganciclovir or oral valganciclovir generally is given for variable periods in cytomegalovirus-seronegative recipients of a transplant from a cytomegalovirus-positive donor.

Medical Complications and Comorbid Conditions

The complications that follow heart transplantation reflect, in part, the premorbid status of a majority of transplant recipients, who have vascular disease and other significant medical conditions.⁶⁷ After 5 years, more than 90% of recipients have hypertension, at least 80% have hyperlipidemia, and more than 30% have diabetes, as shown in **Table 28-5**.⁶⁸ Each year after transplantation, clinically significant CAV—which is the major limitation to long life after transplantation—will develop in a larger number of patients. By 5 years, almost 30% of recipients will have CAV, and at least half will be so afflicted at 10 years, as shown in **Figure 28-8**. Likewise, progressive renal insufficiency is an insidious problem that is only recently being addressed by substitution protocols to limit the administration of calcineurin inhibitors.⁶¹

Malignant Neoplasia

The magnitude of overimmunosuppression in many transplant recipients is illustrated by the prediction of a 30% to 40% incidence of neoplasia in these patients during the past 30 years. The risk of fatal malignant disease progressively increases in the years after transplantation, and there is a substantially higher risk in immunosuppressed patients than in the normal population. Post-transplantation lymphoproliferative disease and lung cancer are the most common fatal malignant neoplasms, as shown in **Table 28-6**.⁶⁸

Diabetes

Patients in whom new-onset diabetes mellitus develops after transplantation are at increased risk for morbidity and mortality. Accumulating evidence suggests that long-term outcomes, including patient survival and graft survival, may be adversely affected. Much of the diabetes that occurs is attributed to the high-dose corticosteroids used early after transplant surgery, but it is now appreciated that the calcineurin inhibitors play an important role as well. Impaired B cell function appears to be the primary mechanism of calcineurin inhibitor-induced new-onset diabetes.

The risk factors for the development of diabetes after transplantation include obesity, increased age, family history of diabetes, abnormal glucose tolerance, and African American or Hispanic descent. Changing trends in the demographics of transplant patients, such as increased age and increased BMI, suggest that these patients may now be at a greater risk for new-onset diabetes than in the past.⁶⁹ Increased BMI increases risk of insulin resistance, and corticosteroids can cause glucose intolerance, insulin resistance, and frank hyperglycemia. African Americans are more likely to develop

TABLE 28-4 Diagnostic Criteria for Antibody-Mediated Rejection

CRITERIA CATEGORY	FINDING(S)	COMMENT
Clinical	Graft dysfunction	
Histologic	Capillary endothelial changes: swelling, denudation, congestion	Required
	Macrophages in capillaries	Required
	Neutrophils in capillaries	More severe cases
	Interstitial changes: edema and/or hemorrhage	More severe cases
Immunopathologic	Immunoglobulin (G, M, and/or A) plus C3d and/or C4d or C1q staining (2 or 2+ intensity) in capillaries by immunofluorescence	One immunopathologic criterion is required
	CD68 positivity for macrophages in capillaries and/or C4D staining of capillaries with 2 to 3+ intensity by paraffin immunohistochemistry	
	Fibrin in vessels	More severe cases
Serologic	Evidence of anti-HLA class I and/or class II antibodies or other antidonor antibody at time of biopsy	Supports other findings

new-onset diabetes mellitus regardless of the immunosuppression used but are particularly susceptible after treatment with tacrolimus.

Hypertension

The excess risk of hypertension is related primarily to the use of calcineurin inhibitors because of both direct effects of the drugs on

the kidney and the associated renal insufficiency that also is highly prevalent. The incidence of hypertension may be lower with tacrolimus than with cyclosporine.⁷⁰ Post-transplantation hypertension is difficult to control and often requires a combination of several anti-hypertensive agents.

Renal Insufficiency

In a large registry of almost 70,000 nonrenal solid organ transplant recipients, the risk for development of chronic renal failure was 16% at 10 years.⁷¹ The various postulated causes of calcineurin inhibitor-associated early renal insufficiency include direct calcineurin inhibitor-mediated renal arteriolar vasoconstriction, increased levels of endothelin-1 (a potent vasoconstrictor), decreased nitric oxide production, and alterations in the kidney's ability to adjust to changes in serum tonicity. Once early renal insufficiency occurs, progressive renal failure has appeared to be inexorable, until recently. A number of new trials are in progress to evaluate the effects on renal function, as well as on rejection episodes, of substituting an m-TOR inhibitor, sirolimus or everolimus, for a calcineurin inhibitor.

Hyperlipidemia

Hyperlipidemia is common after transplantation, as it is in the general population. The concern has been that many studies have demonstrated an association of hyperlipidemia with the development of CAV and cerebrovascular and peripheral vascular disease, with the attendant morbidity and mortality of these vascular disorders. Typically, total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides increase by 3 months after transplantation and then generally fall somewhat after the first year. A number of drugs commonly used after transplantation contribute to the hyperlipidemia observed. Corticosteroids may lead to insulin resistance, increased free fatty acid synthesis, and increased very low-density lipoprotein production. Cyclosporine increases serum LDL cholesterol and binds to the LDL receptor, decreasing its availability to absorb cholesterol from the bloodstream; tacrolimus probably causes less hyperlipidemia. Sirolimus and MMF also have unfavorable effects on lipids. Sirolimus in escalating doses has been shown to result in prominent elevation of triglyceride levels.

Lipid-lowering therapy with any statin, or HMG-CoA reductase inhibitor, was strongly associated with a marked improvement in 1-year survival in the Heart Transplant Lipid registry. In heart transplant recipients, pravastatin and simvastatin have been associated with outcome benefits in survival, severity of rejection, and incidence of CAV.

Cardiac Allograft Vasculopathy

The development of transplant vasculopathy remains the most disheartening long-term complication of heart transplantation, with an

annual incidence rate of 5% to 10%. The prognosis for heart transplant recipients is largely determined by the occurrence of CAV; after the first postoperative year, CAV becomes increasingly important as a cause of death. CAV can develop as early as 3 months after transplantation and is detected angiographically in 20% of grafts at 1 year and in 40% to 50% at 5 years.⁷² In contrast with eccentric lesions seen in atherosclerotic disease, CAV results from neointimal proliferation of vascular smooth muscle cells, so that it is a generalized process. The condition typically is characterized by concentric narrowing that affects the entire length of the coronary tree, from the epicardial to the intramyocardial segments, leading to rapid tapering, pruning, and obliteration of third-order branch vessels. A majority of patients will not experience anginal symptoms, because of denervation of coronary arteries. The first clinical manifestation of CAV may be myocardial ischemia and infarction, heart failure, ventricular arrhythmia, or sudden death.

The causes of transplant vasculopathy are multifactorial. The risk for CAV increases as the number of HLA mismatches and the number and duration of rejection episodes increase. Various nonimmunologic factors, including CMV infection of the recipient, donor or recipient factors (e.g., age, sex, pretransplantation diagnosis), and factors related to surgery (ischemia-reperfusion injury), have been associated with development of CAV and increase the risk for CAV. Classic risk factors for vascular disease, such as smoking, obesity, diabetes, dyslipidemia, and hypertension, also contribute to development of CAV.

In an effort to detect CAV, transplant teams must devise an approach to screen for the disease and, when it is found, to control its progression. Coronary angiography is limited by the fact that CAV produces concentric lesions that affect the distal and small vessels, often before it becomes apparent in the main epicardial vessels. Intravascular ultrasound (IVUS) is the most sensitive imaging technique to study early transplant vasculopathy. IVUS provides quantitative information on vessel wall morphology and lumen dimensions. An increase in intimal thickness of at least 0.5 mm in the first year after transplantation is a reliable indicator of both CAV development and 5-year mortality.⁷³ The inherent invasiveness of IVUS and the cost of the procedure preclude its widespread application, however. Dobutamine stress echocardiography has a high sensitivity (83% to 95%) and specificity (between 53% and 91%) in comparison with angiographic evaluation of CAV and even greater specificity than that for IVUS-detected disease. Most transplant centers do one of these screening tests on an annual basis to assess the risk of new CAV.

Recently, an increased number of trials have been undertaken to examine the efficacy of sirolimus or everolimus in preventing the development or progression of CAV in heart transplant recipients. The precise role of the two drugs in maintenance immunosuppression has not yet been determined, but they are used frequently, with promising results for reduction of coronary intimal thickening once CAV has been detected.

Outcomes after Heart Transplantation Survival

Figure 28-9 depicts the latest data from the International Society for Heart and Lung Transplantation on overall transplant survival.⁷⁴ During the first year after transplantation, early causes of death are graft failure, infection, and rejection, with an overall survival rate at 1 year of 87%. Of interest, although worldwide approaches to the management of the cardiac transplant recipient are substantially different from center to center, the outcomes are surprisingly similar. For example, the 5-, 10-, and 15-year survival rates after heart transplantation were comparable in two centers, one from Nantes, France,⁷⁵ and another from Utrecht, The Netherlands.⁷⁶ Indeed, this phenomenon of similar outcomes despite marked differences in programmatic management may be regarded as a testament to the overall antirejection strategy. Nonspecific graft failure accounted for 41% of deaths during the first 30 days after transplantation, whereas non-cytomegalovirus infection was the primary cause of death during the first year. After 5 years, CAV and late graft failure (31% together),

FIGURE 28-9 Kaplan-Meier adult heart transplant survival in first-time recipients by era, showing a 10-year survival rate of at least 50% and an improvement in survival by era. (From Stehlik J, Edwards LB, Kucheryavaya AY, et al: *The registry of the International Society for Heart and Lung Transplantation: 29th official adult heart transplant report—2012*. *J Heart Lung Transplant* 31:1052, 2012.)

malignant neoplasia (24%), and non-cytomegalovirus infection (10%) are the most prominent causes of death.

Functional Outcomes

By the first year after transplantation surgery, 90% of surviving patients report no functional limitations and approximately 35% return to work.⁷⁷ These figures may change as the demographics of cardiac transplant recipients evolve. Numerous challenges to ensure optimal functional outcomes have been identified, not the least of which is nonreimbursement for cardiac rehabilitation programs by many third-party payers in the United States, along with reluctance of employers in the United States to hire the transplant survivor.

The heart transplant procedure markedly reduces cardiac filling pressures observed in the recipient before transplantation and augments cardiac output. Abnormal maximal cardiac output during exercise may be secondary to denervation, limited atrial function, decreased myocardial compliance from rejection or ischemic injury, and donor-recipient size mismatch. Much of this hemodynamic abnormality may be normalized with regular exercise. Immediately after surgery, a restrictive hemodynamic pattern frequently is observed that gradually lessens over a few days to weeks. Some 10% to 15% of recipients develop a chronic cardiac restrictive-type response during exercise that may produce fatigue and breathlessness. In the absence of parasympathetic innervation, which normally lowers the heart rate, the resting heart rate of a recipient typically is 90 to 115 beats/min. Likewise, beta blockers may further impair exercise response in the transplant recipient and should not be given as first-line agents for treatment of hypertension in this group.

FUTURE PERSPECTIVES

There are many potential reasons why surgery may be considered in patients with heart failure, especially those with ischemic cardiomyopathy. The most widely used surgical procedure for heart failure is CABG, and it is not clear what impact the STICH trial results will have on the frequency of this procedure in the future. Clearly, the immediate perioperative mortality for all surgical procedures has dropped remarkably over the past two decades. The availability of VADs (see Chapter 29) and less invasive procedures such as TAVR (see Chapter 63) will undoubtedly change the scope of heart failure surgery in the upcoming years.

REFERENCES, 599

Mechanical circulatory support (MCS) devices are mechanical pumps designed to assist or replace the function of either the left or right ventricle, or both ventricles, of the heart. Important characteristics of MCS devices include (1) location of the pumping chamber; (2) specific ventricle(s) supported; (3) pumping mechanism; and (4) indicated duration of support, for either temporary (days to weeks) or long-term (months to years) use (**Table 29-1**). Typically, short-term devices are *extracorporeal* or *paracorporeal* pumps (located outside the body), whereas durable devices are *implantable* (intracorporeal) systems.

INDICATIONS FOR MECHANICAL CIRCULATORY SUPPORT AND DEVICE SELECTION

Three indications for MCS are approved by the U.S. Food and Drug Administration (FDA) and reimbursed by the Centers for Medicare & Medicaid Services (CMS): *bridge to recovery* (BTR), *bridge to transplantation* (BTT), and *destination therapy* (DT).

Bridge to Recovery

BTR refers to the use of MCS devices in patients with acute cardiogenic shock or acute decompensated heart failure that is refractory to optimal medical management (OMM), also characterized by a reasonable expectation that the myocardial injury is reversible and that myocardial function will recover during a short period of temporary MCS. The short-term use of MCS for BTR is the most common application of this modality in the United States. Examples of reversible forms of myocardial injury are acute myocardial infarction, acute myocarditis, and postcardiotomy cardiogenic shock resulting from ischemic myocardial stunning. Several types of devices can provide temporary circulatory support in these circumstances, including intra-aortic balloon pumps (IABPs), extracorporeal ventricular assist devices (VADs) (**Fig. e29-1**), and systems for extracorporeal life support (ECLS), previously referred to as extracorporeal membrane oxygenation (ECMO), which provides both cardiac and pulmonary support. Typically, temporary MCS devices are placed percutaneously to facilitate rapid initiation of cardiac support and ease of removal when cardiac function recovers. Some types of extracorporeal VAD systems require major operative procedures with sternotomy for access and placement of the outflow and inflow cannulas and more frequently are initiated in the operating room for postcardiotomy heart failure.

The assumption that the mechanism of myocardial injury is reversible may not be applicable in all clinical situations in which the patient presents with significant hemodynamic compromise and significant organ injury. Temporary MCS may be instituted in good expectation of clinical improvement, with subsequent recognition that myocardial recovery is unlikely to occur or has not occurred despite an extended period of support. In such situations, temporary MCS can be continued as a bridge to placement of a long-term, implantable VAD (bridge to bridge [BTB] application), or as a bridge to heart transplantation. The use of temporary MCS in this fashion is not an approved indication but occasionally may be appropriate, owing to the inherent difficulties in accurately assessing the potential for myocardial recovery in all clinical settings. As a rule, patients should be excluded from consideration for temporary MCS if myocardial recovery is unlikely and the option of heart transplantation or implantation of a long-term, durable VAD is not feasible. Under these circumstances, MCS generally is considered futile and should not be instituted.

Bridge to Transplantation

The second indication for MCS applies to patients presenting with cardiogenic shock or decompensated advanced heart failure refractory to OMM in whom myocardial function is unlikely to recover (e.g., long-standing ischemic, valvular, or idiopathic cardiomyopathy; severe acute myocardial infarction or myocarditis), and who are considered eligible for heart transplantation. Durable, implantable MCS devices that are designed for long-term use and permit untethered patient mobility and discharge from the hospital are appropriate devices for BTT indication (see **Figs. 29-1 and 29-2**). A major operative procedure, including cardiopulmonary bypass, is required for placement in most instances. These devices ideally are placed in patients with significant symptoms of heart failure who are either receiving intravenous inotropes or who are not on inotropes but have limiting symptoms at rest, and in whom hemodynamics are stable and end-organ function is preserved. Selected patients with acutely unstable hemodynamics and compromised organ function may be better served by a BTB strategy consisting of temporary MCS followed by subsequent placement of a durable MCS device for those who respond with improvements in hemodynamics and organ function.

Destination Therapy

The feasibility of durable, implantable MCS devices to provide long-term support demonstrated through the BTT experience, prompted further expansion of indications for durable, implantable MCS devices

FIGURE e29-1 Extracorporeal VAD. An example of an extracorporeal MCS device providing biventricular assist. The external blood pumps, each supporting one ventricle, are actuated by a large console providing pneumatic drive. **Inset,** Cannulas are positioned for biventricular support. *Left ventricle:* A cannula is positioned in the right superior pulmonary vein (RSPV) and drains blood from the left atrium and pumps it back to the aorta. *Right ventricle:* A cannula positioned in the right atrium drains blood from the heart and pumps it to the main pulmonary artery.

TABLE 29-1 Terminology Describing Characteristics of Mechanical Circulatory Support Devices*

PUMP LOCATION	VENTRICLE SUPPORTED	INTENDED USE	PUMP MECHANISM
Extracorporeal pump located outside the body	LV support (LVAD)	<i>Short-term:</i> Days to weeks (BTR indication) Patient remains hospitalized Patient tethered to pump	Pulsatile, volume displacement Pneumatic actuation Electrical actuation
Intracorporeal pump implanted within the body	RV support (RVAD)	<i>Long-term:</i> Months to years (BTT or DT indication) Patient discharged with untethered, "hands-free" mobility	Continuous flow rotary pump Axial flow design (flow of blood is along the axis of symmetry of the pump) Bearing support of impeller (mechanical pivot) Magnetic or hydrodynamic levitation of impeller (bearingless design)
Paracorporeal pump located out-side but adjacent to body	Biventricular support (BiVAD)		Continuous flow rotary pump Centrifugal flow design (flow of blood from the center to periphery of the pump) Bearing support of impeller Magnetic or hydrodynamic levitation of impeller (bearingless design)
Orthotopic position—TAH	Biventricular replacement—TAH		

*Columns represent characteristics of mechanical circulatory devices. Columns are distinct characteristics and are not linked to adjacent columns
LVAD = left ventricular assist device; RVAD = right ventricular assist device; TAH = Total Artificial Heart.

FIGURE 29-1 The HeartMate VE/XVE (A), shown here as the electrical version, and the Novacor LVAS (B) emerged as the most successful implanted LVADs in the late 1980s and 1990s. (Reprinted with permission of Thoratec Corporation.)

FIGURE 29-2 The HeartMate II device has an inlet cannula of sintered titanium and a Dacron outflow cannula, shown here with bend relief to reduce kinking and injury at re sternotomy (A). The system provides patient mobility (B). (Reprinted with permission of Thoratec Corporation.)

as a permanent alternative to heart transplantation. DT is the application of MCS in patients with chronic refractory symptoms of advanced heart failure that result from irreversible forms of either nonischemic or ischemic cardiomyopathy and who are ineligible for heart transplantation. Use of durable, implantable devices that permit untethered “hands-free” patient mobility at home is appropriate in this clinical situation. A major operative procedure is required for placement of these implantable pumps, which, as in the setting of BTT, are ideally used in patients with significant symptoms of advanced heart failure but stable hemodynamics and no manifestations of significant organ injury, debilitation, or cachexia. The benefit of MCS for DT, in terms of survival, function, and quality of life, for the treatment of chronic advanced heart failure was established in a prospective, randomized trial known as REMATCH (Randomized Evaluation of Mechanical Assistance in the Treatment of Congestive Heart Failure).¹ REMATCH evaluated the use of an implantable left VAD (LVAD) compared with OMM for refractory chronic advanced heart failure. LVAD therapy halved (relative risk, 0.52; 95% confidence limit, 0.34 to 0.78) the mortality seen in the control population (92% at 2 years) treated with OMM. Despite serious adverse events (e.g., stroke, infection, bleeding, device malfunction) attributable to MCS, LVAD recipients experienced a better quality of life than those in the OMM group.

Patients evaluated for DT must meet specific criteria for reimbursement from CMS that include (1) ineligibility for heart transplantation; (2) significant functional limitations consistent with New York Heart Association (NYHA) class IIIB or IV symptoms for 45 of the preceding 60 days despite the use of maximally tolerated doses of drugs outlined in guidelines for heart failure treatment; (3) left ventricular ejection fraction (LVEF) less than 25%; and (4) a peak exercise oxygen consumption (peak VO_2) of 14 mL/kg/min or less, unless the patient is dependent on intravenous inotropes for 14 days or IABP for 7 days.² Although the current reimbursement framework requires determination of DT or BTT status, it is often not possible when assessing VAD candidacy to accurately determine future transplant eligibility. Many patients present with hemodynamic compromise, significant pulmonary hypertension, organ injury, cachexia or debilitation that represent relative contraindications to heart transplantation but may be reversible with a period of MCS. The terms “bridge to candidacy” (BTC) and “bridge to decision” (BTD) reflect the unknown efficacy of MCS therapy to reverse those clinical conditions that represent relative barriers to heart transplantation. Conversely, patients receiving MCS for BTT indication may experience significant complications after implantation of an MCS device that could adversely affect transplantation candidate status. Although BTC or BTD more accurately reflects the dynamic state of transplant eligibility, BTC and BTD are not recognized by the FDA as an approved indication for use of MCS therapy (nor by CMS as eligible for coverage). In the future, it is likely that a unifying indication and coverage determination will encompass MCS therapy with durable devices for long-term support independent of transplant eligibility.

The intended use and indication for MCS have significant influences on the appropriate device selection and use. The decision to initiate MCS must include an analysis of the intended use and clinical setting, along with patient variables and conditions, the type of MCS devices available, and FDA approval, medical society guidelines for use of the device and financial considerations.

OVERVIEW OF ENGINEERING DESIGNS OF VENTRICULAR ASSIST DEVICES

MCS pumps may be positioned extracorporeally (outside the body) (see Fig. e29-1) or intracorporeally (contained within the body), as with a biventricular assist device (BiVAD), a right

ventricular assist device (RVAD), or, more commonly, an LVAD. The pump characteristic further substratifies them into *pulsatile* or *non-pulsatile*. The first-generation pulsatile volume displacement pumps were large, preload-dependent, and associated with decreased durability, such as the HeartMate XVE and Novacor LVAS³ (Fig. 29-1). The second-generation continuous flow nonpulsatile pumps are smaller in profile, capable of a similar degree of pumping support (10 liters/minute), and more durable and are functionally dependent on both preload and afterload—for example, the HeartMate II (Fig. 29-2), HeartWare (Fig. 29-3), and Jarvik 2000 (Fig. 29-4).⁴⁻⁶

Additional content on this topic, including **Figures e29-2 through e29-6**, is available in the online supplement for this chapter entitled “Engineering Designs of Ventricular Assist Devices.”

The improvements in design attributes of the third generation of rotary pumps with centrifugal design, including decreased mechanical wear, operation at low flow, and perceived improved potential for hemocompatibility, are currently under development. To date, however, clinical data that demonstrate the superiority of one design over the other are lacking.

PATIENT SELECTION, PATIENT COMORBIDITY, AND TIMING OF MECHANICAL CIRCULATORY SUPPORT INTERVENTION

Timing the initiation of MCS is crucial to patient outcome. There are no absolute hemodynamic criteria to meet in order to initiate MCS for any indication. Generally, patients presenting with acute forms of

FIGURE 29-3 The HeartWare HVAD (HeartWare International, Inc., Framingham, Mass) is an example of a third-generation continuous flow rotary pump with centrifugal design incorporating magnetic and hydrodynamic levitation of the rotor (bearingless motor design). **A**, The device consists of an inflow cannula that inserts into the left ventricle, pump, and outflow graft (not shown) that attaches to the ascending aorta. A percutaneous driveline traverses the skin and attaches to an external controller and power source. **B**, The internal impeller is levitated by magnetic forces positioned in the impeller and central post. Hydrodynamic forces generated by the top surface of the impeller stabilize impeller position.

FIGURE 29-4 **A**, The Jarvik 2000 (Jarvik Heart Corp., New York) is an example of a second-generation continuous flow rotary pump with axial design and bearing support of the internal impeller (mechanical pivot design). **B**, The unique feature of the Jarvik 2000 design is the elimination of the inflow cannula and insertion of the pump directly within the left ventricle. The outflow graft is designed to permit positioning to the ascending or descending aorta, allowing flexibility with the operative approach to the left ventricle through either a sternotomy or a left lateral thoracotomy. (From Thunberg CA, Gaitan B, Arabia FA, et al: Ventricular assist devices today and tomorrow. *J Cardiothorac Vasc Anesth* 24:656, 2010.)

myocardial injury exhibit recognizable changes in hemodynamics. A cardiac index less than 1.8 to 2.2 L/min/m², systolic blood pressure less than 90 mm Hg, pulmonary capillary wedge pressure greater than 20 mm Hg, right atrial pressure greater than 18 to 20 mm Hg, and evidence of poor tissue perfusion, reflected by oliguria, rising creatinine and liver transaminases, mental status changes, or cool extremities, despite the use of OMM, constitute general guidelines for initiation of MCS. Patient history and overall clinical setting also need to be considered in the decision. When the patient reaches this degree of hemodynamic compromise, the risk of death is substantial and is in excess of 50% at 30 days despite the availability of OMM, invasive circulatory monitoring, thrombolysis, and IABP support.⁷

More subtle indications to initiate MCS may be present, particularly in the group of patients suffering from chronic advanced heart failure who are being evaluated for BTT or DT. These indications include resting tachycardia, progressive organ dysfunction, and persistent significant symptoms of heart failure resulting in limited functional capacity and poor quality of life despite OMM with or without inotrope therapy. Deterioration in end-organ function or progressive decline in functional performance may occur in the absence of a significant change in hemodynamic parameters (chronic adaptation to low cardiac output). Ambulatory patients with NYHA class IV symptoms who do not tolerate OMM for advanced heart failure and experience renal insufficiency or hypotension in the setting of optimal dosages of angiotensin-converting enzyme (ACE) inhibitors or beta blockers may need evaluation for MCS therapy. Patients who require inotrope therapy or who do not tolerate inotrope therapy as a result of refractory ventricular arrhythmias or those who have life-threatening coronary anatomy and unstable angina not amenable to revascularization, and who are at risk of imminent death (hours, days or weeks), may be considered for MCS without necessarily meeting hemodynamic criteria.

As noted earlier, generally, patients should be excluded from consideration for MCS if cardiac recovery is unlikely and the options of heart transplantation and DT are not feasible. Under these circumstances, MCS support generally is considered futile. More general contraindications to initiating MCS include irreversible renal, hepatic or respiratory failure, sepsis, and significant cognitive deficit.

Renal Function

Renal dysfunction has consistently been one of the greatest risks for morbidity and mortality with the use of MCS. Renal dysfunction often is secondary to decreased perfusion of the kidney in cardiogenic shock or advanced heart failure but also may be due to nephrotoxic effects of drugs utilized for heart failure therapy, intrarenal hemodynamic derangements reflecting overactivity of the renin-angiotensin-aldosterone and sympathetic nervous systems in advanced heart failure, or complications of noncardiac comorbidity. In patients with shock or advanced heart failure, it is difficult to assess the reversibility of renal dysfunction. Acute onset of renal failure requiring renal replacement therapy is not necessarily a contraindication to initiate short-term MCS but may be a greater obstacle to successful long-term support with implantable devices for BTT and in particular, DT. In the setting of cardiogenic shock with acute renal failure, establishing normal hemodynamics with MCS may resolve the renal failure in a relatively short period of time. Thus the degree and duration of cardiogenic shock, along with the patient's baseline renal function, must be considered in estimating the probability of recovery of renal function.

Pulmonary Function

Heart failure may be associated with a restrictive pattern on pulmonary function testing. However, this often improves with removal of interstitial fluid and intrathoracic effusions after placement of an MCS device and resolution of lung congestion. Patients with a long history of smoking or a history of other intrinsic lung disease with significant abnormalities on pulmonary function testing—for example, less than 50% of predicted normal value for forced vital capacity (FVC), forced expiratory volume at 1 second (FEV₁), or diffusion capacity for carbon monoxide (DLCO)—should undergo high-resolution computed tomography (CT). Patients with low oxygen saturation (<92%) on room air also require evaluation with echocardiography to rule out a right-to-left shunt from an atrial septal defect or patent foramen ovale; if

results are negative, spiral (helical) CT or radionuclide scanning to rule out thromboembolic disease is warranted. Patients with severe pulmonary disease may have an elevated pulmonary vascular resistance that is fixed (not responsive to pulmonary artery vasodilators). High fixed pulmonary vascular resistance (generally >6 Wood units) represents a contraindication to heart transplantation and consequently to use of MCS for BTT indication. Perioperative hypoxia secondary to significant underlying lung disease also may contribute to pulmonary vasoconstriction, leading to RV failure after institution of VAD support. Sleep apnea is present in a significant number of patients with heart failure, which may contribute to pulmonary hypertension. Moderate elevations in pulmonary vascular resistance can be encountered in patients with cardiogenic shock; such increased resistance does not preclude successful use of MCS if reversibility or lowering of the pulmonary vascular resistance is achieved with inotropes or pulmonary vasodilators.

Hepatic Function

Previous studies have reported that total bilirubin level and hepatic cellular enzyme levels higher than three times normal are independent risk factors for adverse outcomes. The etiology of the hyperbilirubinemia may be multifactorial, including "cardiac congestion" or cirrhosis, cholestatic jaundice, or a combination of causative disorders. Abnormal liver function often is associated with abnormal coagulation factors, as well as low serum albumin. Attempts should be made to normalize all indices of liver function and the cause(s) of any abnormalities preoperatively. The presence of portal hypertension with liver cirrhosis is a contraindication to initiating MCS support. A history of significant alcohol use should be ruled out in all potential candidates for MCS therapy, especially those with abnormal liver function. Patients also should be tested for previous infection with hepatitis A, B, or C viruses or others. Ultrasound visualization of the liver is a good screening test in patients with significant hepatomegaly to rule out infiltrative disease, mass, or other pathologic condition that may warrant biopsy. Decrease in hepatic congestion and recovery of synthetic functions of the liver can occur with institution of MCS.

Right Ventricular Function

Patients with the advanced heart failure frequently have coexisting RV failure. This entity may be a major contributor to mortality or morbidity after initiation of MCS.^{8,9} RV failure in most patients is a result of LV failure. Patients with a nonischemic etiology often present with significant RV failure and may have a three- to fourfold increased risk of requiring both LV and RV support. Patients who require BiVAD support have significantly higher preoperative creatinine and total bilirubin levels and a greater need for mechanical ventilation before MCS device insertion as compared with patients requiring LVAD support only. The need for BiVAD support is associated with substantially worse survival with both short-term and long-term MCS devices as a consequence of a greater degree of compromise of preoperative organ function.¹⁰ RV failure is a prominent factor leading to renal dysfunction after LVAD implantation, because right atrial pressures higher than 20 mm Hg lead to changes in glomerular filtration from cortical to medullary nephrons, with secondary reduction in urine output and resistance to diuretic therapy. Preoperative optimization of RV function with a goal right atrial pressure ideally less than 15 mm Hg is important in reducing the need for postoperative RV support. The higher the left atrial or wedge pressure at the time of device implantation, the greater the benefit to the right ventricle and pulmonary artery pressure when the left ventricle is totally unloaded and left atrial pressure falls. Recovery of RV function, however, may lag for several days, because total decompression of the left ventricle allows a significant shift of the interventricular septum toward the left ventricle, with further distention and dysfunction of the right ventricle.¹¹

Coagulation

Coagulopathy is a significant risk factor and a common abnormality noted in patients with refractory heart failure. An abnormal international normalized ratio (INR) in the absence of warfarin use is of added concern, because it may reflect chronically high right atrial pressures, leading to hepatic congestion and, ultimately, to hepatic fibrosis and cirrhosis. Prolonged abnormal INR and low platelet count combined with use of anticoagulation or antiplatelet therapy are associated with significant perioperative bleeding, requiring multiple transfusions, leading to increased pulmonary vascular resistance, RV failure, decline in renal function, hemodynamic instability, and multiple-organ failure. In addition, patients with severe heart failure commonly have

a nutritional basis for abnormal coagulation owing to depletion of several specific coagulation factors, such as factor VII. The minimum preoperative screen for coagulation abnormalities should include prothrombin time (PT), partial thromboplastin time (PTT), INR, platelet count, platelet aggregation studies, and, in view of the high likelihood of previous heparin exposure, a heparin-induced thrombocytopenia (HIT) assay. The presence or development of HIT is associated with a high risk of bleeding as well as thrombosis of MCS devices.

Nutrition

Nutrition is an important contributor to overall outcome with MCS. A low serum albumin (<3.3 mg/dL) was the prominent risk factor for mortality and was associated with a relative increase in risk of 6.6-fold in the study by Lietz and colleagues,^{12,13} who evaluated outcomes with LVAD therapy for DT. Significant nutritional deficiency often is associated with poor wound healing and increased risk of infection and impaired T lymphocyte cellular function, as manifested by cutaneous skin test anergy. Body habitus is a marker of nutrition and an important consideration in patient selection and is reliably defined by body mass index (BMI). Patients whose BMI is either below 22 or above 36 are at risk for perioperative complications, but outcomes are more adversely affected by cachexia than by obesity.^{12,13} Cachexia often is due to poor appetite secondary to elevated levels of tumor necrosis factor (TNF) and other cytokines, limitations in exertion and increased work of breathing, and early satiety in patients with significant hepatomegaly or bowel edema.^{12,13} Cessation of calorie intake for as little as 24 hours may be associated with a 50% reduction in production of critical proteins needed for wound repair. When feasible, delay in instituting MCS therapy for several weeks may be warranted, to allow improvement in nutritional status, either by ingestion of various oral nutritional supplements or with enteral feedings delivered through a small feeding tube, preferentially with nocturnal feeding in patients unable to consume adequate calories during the day. Early, aggressive caloric supplementation in the postoperative period also is critical to preventing or correcting malnutrition.

Other Important Medical Considerations

Other important medical considerations in instituting MCS include the presence or absence of significant aortic, mitral, or tricuspid valve disease,¹⁴⁻¹⁶ coronary artery disease, and atrial and ventricular arrhythmias, as well as intracardiac shunts.

Additional content on these topics is available in the online supplement for this chapter entitled “Important Medical Conditions in Instituting Mechanical Circulatory Support.”

PATIENT OUTCOMES WITH MECHANICAL CIRCULATORY SUPPORT

Temporary Mechanical Circulatory Support

Temporary MCS (**Table e29-1**) is indicated in patients with cardiogenic shock refractory to medical therapy when *rapidly achieved* augmentation of cardiac output and reduction of ventricular filling pressures are required to sustain life. When used in the setting of medically refractory myocarditis or takotsubo cardiomyopathy, temporary MCS may provide time for spontaneous recovery and discontinuation of MCS. When cardiogenic shock complicates long-standing heart failure, temporary MCS can provide the time needed for patients, family members, and physicians to make critical decisions about long-term MCS and heart transplantation. Patients with heart failure severe enough to warrant long-term MCS but with reversible clinical characteristics (e.g., coagulopathy from hepatic congestion, acute renal failure

from low cardiac output and high right atrial pressure, hypoalbuminemia resulting from cardiac cachexia and bowel edema) that put them at high risk for perioperative death with a long-term device may benefit from temporary MCS if their risk profile could be substantially improved with temporary MCS to the extent that they would become good candidates for a durable MCS device. The clinical evaluation of temporary MCS devices for treatment of cardiogenic shock generally has not required randomized clinical trial design but has relied on the use of prospective, single-arm observation studies to validate device design, safety, and efficacy.

Extracorporeal Life Support/Extracorporeal Membrane Oxygenation

Numerous large clinical series have reported successful use of ECLS for cardiac and/or respiratory support in adult, pediatric, and neonatal patients. In the largest series to date, Bartlett and colleagues at the University of Michigan reported on outcomes for 1000 patients supported with ECLS from 1980 through 1998.¹⁷ Cardiac failure was the indication for support in 146 cases. Survival to hospital discharge occurred in 33% of adult patients (31 cases) and in 48% of pediatric patients (105 cases). Survival in adult patients was improved by using ECLS as a bridge to placement of longer-term implantable devices in patients who did not demonstrate early recovery of myocardial function. Conversely, the availability of long-term implantable devices has extended the use of ECLS in situations where recovery of myocardial function is unlikely.

TandemHeart pVAD

In a randomized comparison of IABP with a paracorporeal VAD (pVAD), the Tandem Heart pVAD, Thiele and colleagues reported a more effective improvement in cardiac power index as well as other hemodynamic and metabolic variables with the Tandem Heart pVAD compared with the IABP.¹⁸ Complications such as severe bleeding and limb ischemia, however, were encountered more frequently after VAD support. Thirty-day mortality rates were similar between the groups, but the study was underpowered to compare mortality between groups.

Impella

In a prospective, randomized clinical trial comparing the Impella 2.5 (**Fig. 29-5**) and an IABP, cardiac index was significantly increased in patients with the Impella 2.5 compared with patients supported with an IABP.¹⁹ Overall mortality rates at 30 days were similar in both groups, but the study was not adequately powered to assess for a mortality difference.

Despite the absence of suitably powered randomized clinical trials demonstrating a mortality benefit over IABP therapy, the use of temporary MCS devices in patients with cardiogenic shock is likely to continue. In comparison with an IABP, these devices provide a much larger increment in cardiac output and superior LV unloading.

FIGURE 29-5 **A**, The Impella VAD is a catheter-based, impeller-driven, microaxial flow pump. **B**, The device is inserted percutaneously or by surgical placement through the femoral artery or ascending aorta and positioned across the aortic valve. (From Thunberg CA, Gaitan B, Arabia FA, et al: Ventricular assist devices today and tomorrow. *J Cardiothorac Vasc Anesth* 24:656, 2010.)

TABLE e29-1 Temporary Mechanical Circulatory Support Devices*

DEVICE	PUMP MECHANISM	PUMP ENERGY SOURCE	METHOD OF PLACEMENT	VENTRICLE SUPPORTED	DEGREE OF SUPPORT
IABP (Several manufacturers)	Counterpulsation	Pneumatic	Percutaneous placement via femoral artery or operative placement in ascending aorta	Principal effect: reduction of LV afterload	Partial-support device
Abiomed (AB5000 Abiomed Corp., Danvers, Mass)	Pulsatile, volume displacement	Pneumatic	Operative placement	Right, left, or biventricular support	Full-support device (4 to 6 liters/min)
Extracorporeal Life Support (ECLS) (Several manufacturers depending on pump selected)	Continuous flow rotary pump with centrifugal design	Variable Depends on pump utilized for the ECLS circuit	Percutaneous or operative placement	Venous-arterial configuration Partial unloading of right and left ventricles by reduction in preload with oxygenation of blood	Full-support device (4 to 6 liters/min)
CentriMag VAD (Thoratec Corp., Pleasanton, Calif)	Continuous flow rotary pump with centrifugal design (magnetic levitation; no bearing)	Electric motor	Operative placement	Right, left, or biventricular support	Full-support device (4 to 6 liters/min)
TandemHeart pVAD (CardiacAssist Corp., Pittsburgh)	Continuous flow rotary pump with centrifugal design (bearing support of impeller)	Electric motor	Percutaneous placement Requires trans-septal placement of cannula for left atrial drainage Arterial return to femoral artery	LV support [†]	Partial-support device (2 to 4 liters/min)
Impella 2.5, CP, 5.0, or LD (Abiomed Corp., Danvers, Mass)	Continuous flow rotary pump with microaxial design (bearing support of impeller)	Electric motor	Percutaneous via femoral artery (Impella 2.5, CP, or 5.0) or operative placement via aorta or axillary depending on device size (Impella LD) Placement across the aortic valve (Impella LD) Inflow from the left ventricle and outflow in the ascending aorta	LV support [‡]	Partial-support device (1 to 3 liters/min) for Impella 2.5 or CP Full-support device (3-5 liters/min) for Impella 5.0 or LD

*The table includes representative MCS devices and is not meant to be an exhaustive listing of all devices currently available in the United States or internationally.

[†]Values of cardiac support represent approximate ranges and capabilities of the device.

[‡]An investigational device designed for RV support is in clinical evaluation.

Intra-aortic Balloon Pump

The efficacy of IABP counterpulsation was recently evaluated in SHOCK II, a randomized, prospective, open-label, multicenter trial comparing IABP therapy with best available medical therapy for treatment of acute myocardial infarction complicated by cardiogenic shock.²⁰ All patients were expected to undergo early revascularization (by means of percutaneous coronary intervention or bypass surgery). At 30 days, 119 patients in the IABP group (39.7%) and 123 patients in the control group (41.3%) had died (relative risk with IABP, 0.96; 95% confidence interval [CI], 0.79 to 1.17; $P = 0.69$). No significant differences were found in secondary endpoints or in process-of-care measures, including the time to hemodynamic stabilization, the length of stay in the intensive care unit, serum lactate levels, the dose and duration of catecholamine therapy, and renal function. The use of IABP counterpulsation did not significantly reduce 30-day mortality in patients with acute myocardial infarction complicated by cardiogenic shock for whom an early revascularization strategy was planned.

Devices Intended for Long-term Mechanical Circulatory Support

Table 29-2 summarizes the characteristics of durable MCS devices intended for long-term use.

Ventricular Assist Devices

Thoratec HeartMate II

The HeartMate II is the most evaluated MCS device to date, with more than 13,000 implantations worldwide.^{4,21-24} Patient outcomes after implantation of the HeartMate II have been extensively evaluated in five major scientific reports on use of the device for BTT and DT indications within the context of pre- and postapproval clinical trials (**Table 29-3**).^{4,21-24} Several of these trials are summarized next.

(Additional content on this topic is available in the online supplement for this chapter entitled “Clinical Trials with the HeartMate II Device.”)

The HeartMate II Pivotal Trial for BTT was an FDA-approved, prospective, nonrandomized, multicenter study of 133 patients with

end-stage heart failure who were on a waiting list for a heart transplant and received implantation of the HeartMate II device. The primary endpoint was a composite of the proportions of patients who, at 180 days, had undergone transplantation, were explanted for cardiac recovery, or had ongoing MCS with the HeartMate II while remaining eligible for transplantation. Of the 133 patients receiving support with the HeartMate II device, the principal outcomes were observed in 100 patients (75%).⁴ At 3 and 6 months, device support with the HeartMate II was associated with significant improvement in functional status (NYHA functional class and 6-minute walk test distance) and in quality of life (Minnesota Living with Heart Failure and Kansas City Cardiomyopathy questionnaires).⁴ Major adverse events included postoperative bleeding, stroke, right heart failure, percutaneous lead infection, and device malfunction (**Table e29-2**).

The HeartMate II DT Pivotal Trial randomly assigned 200 patients with NYHA class IIIB to IV symptoms and an LVEF of 25% or less to receive a HeartMate II or a HeartMate XVE.²² Eligible patients also had to have either a maximal oxygen consumption not exceeding 14 mL/kg/min, require treatment with intravenous inotropic agents for 14 days or longer, or an intra-aortic balloon pump for 7 days or longer.²² The primary endpoint was a composite of survival to 24 months without disabling stroke or the need for an operation to repair or replace the device. A greater than fourfold increase was observed in the percentage of HeartMate II patients who successfully reached the primary endpoint (46% versus 11%; $P < .001$).⁶ All adverse events were less frequent among patients receiving the HeartMate II, with significant reductions in sepsis, device-related infections, right-sided heart failure, renal failure, and rehospitalizations. Changes in functional capacity, 6-minute walk distance, and quality of life scores were similar between groups, suggesting that the improvements seen in these metrics in VAD-supported patients are more closely linked to the favorable effects of increasing the cardiac output and lowering the left-sided filling pressures rather than the characteristics of blood flow.

The introduction of continuous flow technology into clinical practice was a milestone in the field of MCS therapy and led to significant improvements in survival and reduction of serious major adverse events, especially in the area of device malfunctions. Compared with pulsatile flow devices, continuous flow technology demonstrated at least equal efficacy regarding hemodynamic support, ability to improve renal and hepatic function, rates of heart transplantation,

TABLE 29-2 Long-term Durable Mechanical Circulatory Support Devices*

DEVICE	PUMP MECHANISM	PUMP ENERGY SOURCE	METHOD OF PLACEMENT	VENTRICLE SUPPORTED	INDICATION
Thoratec pVAD (Thoratec Corp., Pleasanton, Calif)	Pulsatile, volume displacement	Pneumatic Patient tethered to portable drive unit	Operative	Right, left, or biventricular support Paracorporeal pump position	BTT or BTR
Thoratec iVAD (Thoratec Corp.)	Pulsatile, volume displacement	Pneumatic Patient tethered to portable drive unit	Operative	Right, left, or biventricular support Implantable pump requiring preperitoneal pocket	BTT
HeartMate II (Thoratec Corp.)	Continuous flow rotary pump with axial design (bearing support of impeller)	Electric motor Power to pump delivered via percutaneous lead with external power source and computer controller	Operative	Left ventricle Implantable pump requiring preperitoneal pocket	BTT, DT
HVAD [†] (HeartWare International, Inc., Framingham, Mass)	Continuous flow rotary pump with centrifugal design (magnetic levitation; no bearing)	Electric motor Power to pump delivered via percutaneous lead with external power source and computer controller	Operative	Left ventricle Implantable pump with intrapericardial placement No preperitoneal pocket required	BTT
CardioWest TAH-t (SynCardia Systems, Inc., Tucson)	Pulsatile, volume displacement (50-cc and 70-cc displacement devices)	Pneumatic Patient tethered to portable drive unit	Operative	Biventricular support Orthotopic placement with removal of both ventricles	BTT DT [‡]

*Currently undergoing clinical evaluation for DT indication in the United States.

and overall patient survival. Of importance, significantly fewer deaths were observed during late follow-up (6 to 18 months) than those observed with the HeartMate XVE, suggesting that the incidence of major events contributing to fatalities, such as stroke, infection, and device malfunction, was significantly lower. Excellent late survival on LVAD support was maintained in the absence of continuing high rates of attrition to heart transplantation, suggesting that significant complications were not treated with urgent transplantation. This result probably can be attributed in part to the improved durability of the device and the markedly reduced need for replacement.

HVAD (HeartWare Ventricular Assist Device)

The HVAD has undergone clinical evaluation in the United States for BTT indication in a prospective, nonrandomized clinical trial, ADVANCE^{25,26} (see Table 29-3). The unique feature of ADVANCE was the use of a contemporaneous, observational control arm derived from registrants entered into INTERMACS. The primary outcome in ADVANCE was success defined as survival on the originally implanted device, transplantation, or explantation for ventricular recovery at 180 days and was evaluated for both noninferiority and superiority. A total of 140 patients received the investigational pump, and 499 patients received a commercially available pump implanted contemporaneously. Success was achieved in 90.7% of patients on the investigational pump and in 90.1% of control subjects, establishing the noninferiority of the investigational pump ($P < .001$; 15% noninferiority margin). At 6 months, median 6-minute walk distance increased by 128.5 meters, and both disease-specific and global quality of life scores improved significantly. The HVAD was approved for use in the United States for the BTT indication in 2012 and currently is undergoing study in the United States for the DT indication.

Total Artificial Heart

SynCardia CardioWest TAH-t

Another option for MCS is the total artificial heart (TAH). The 70-mL stroke volume version of the SynCardia CardioWest TAH-t (Fig. 29-6)

**FIGURE 29-6** The SynCardia TAH-t.

was evaluated in a large, prospective, nonrandomized trial conducted in five centers for BTT indication in 81 patients at risk for imminent death from irreversible biventricular cardiac failure.²⁷ The study cohort was compared with a nonrandomized, observational control cohort of 35 patients. The primary study endpoints included

the rates of survival to heart transplantation and survival after transplantation. The rate of survival to transplantation was 79% (95% CI, 68% to 87%). Of the 35 patients in the control cohort who met the same entry criteria but did not receive the TAH-t, 16 (46%) survived to transplantation ($P < .001$). Overall, the 1-year survival rate among the patients who received the TAH was 70%, compared with 31% among the control subjects ($P < .001$). After transplantation, 1-year and 5-year survival rates among patients who had received the TAH were 86% and 64%.²⁷ The SynCardia CardioWest TAH-t was approved by the FDA for BTT in 2007.

INTERAGENCY REGISTRY OF MECHANICALLY ASSISTED CIRCULATORY SUPPORT

An important milestone in the advance of MCS therapy has been the development of the National, Heart, Lung and Blood Institute (NHLBI)-sponsored national registry, the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS). INTERMACS is the largest available data repository for the study of durable MCS outcomes.²⁸ INTERMACS represents a collaboration among the NHLBI, the FDA, the CMS, device manufacturers, and the professional community and began prospective patient enrollment and data collection in June 2006. In March 2009, CMS and the U.S. Department of Health and Human Services mandated that all U.S. hospitals approved for use of MCS for DT enter MCS patient data into INTERMACS for all noninvestigative MCS devices approved by FDA. Since the inception of INTERMACS, the ongoing evolution of strategies for device application and the types of available devices has continued to refine the landscape of MCS. The major limitation of the INTERMACS registry is the inability to enter patient information on investigational devices currently in evaluation in the United States and the need for informed consent that represents a barrier to capture of all patients receiving MCS therapy. To date, data on over 8000 patients receiving durable MCS therapy have been reported to INTERMACS.²⁸ The overall survival rate for all patients undergoing primary implantation of a durable MCS device is approximately 80% at 1 year and 70% at 2 years²⁸ (Figure 29-7). Survival for patients undergoing primary implantation with an LVAD was superior to biventricular support or support after implantation of a TAH (data not shown).

One of the most important contributions to the field has been the development of a subjective classification system based on severity of illness, termed "INTERMACS Patient Profiles," which range from

Profile 1 (critical cardiogenic shock) to Profile 7 (advanced NYHA class III heart failure) (Table 29-4).²⁸ This classification system has added enhanced resolution of patient outcomes in the advanced stages of heart failure or cardiogenic shock above that offered by the NYHA classification of heart failure symptoms. INTERMACS Patient Profiles have correlated severity of illness with outcome and have provided additional information on appropriate timing of intervention with durable, implantable MCS devices. Patients undergoing implantation of an MCS device in the presence of critical cardiogenic shock (INTERMACS Patient Profile 1) have worse outcomes compared with MCS device implantation in patients with more stable forms of advanced heart failure (INTERMACS Patient Profile levels 2 through 7)²⁸ (Fig. 29-8). Patients with significant organ dysfunction at the time of MCS device implantation, accompanied by a greater degree of hemodynamic compromise, are at significantly more likely to require BiVAD support and are at higher risk for major adverse events and significantly higher risk for death during use of MCS devices.

FUTURE PERSPECTIVES

Recent rapid technological advancements and successful clinical applications of MCS have provided a major impetus to extending the use of this modality. In this regard, a number of important initiatives currently in progress will contribute significantly to future directions in MCS therapy. These initiatives include (1) introduction of new MCS devices that focus on miniaturization and biventricular support applications; (2) implementation of partial-support MCS devices and regimens; (3) design of fully implantable MCS devices, with elimination of the percutaneous lead and introduction of wireless energy transfer; (4) specific developments in the field of pediatric MCS including appropriately sized and designed MCS devices, clinical trials, and national registry development; (5) evaluation of MCS therapy in patients with less advanced heart failure; and (6) harmonization of the global MCS experience through international registry initiatives.

A number of new MCS devices are expected to be introduced into clinical evaluation in the near future. These devices include the HeartMate III (Thoratec Corp., Pleasanton, Calif) (Fig. e29-7) and the MVAD (HeartWare International, Inc., Framingham, Mass) (Fig. e29-8).^{6,29,30} The HeartMate III is an implantable, continuous flow rotary pump with centrifugal design intended for long-term MCS.^{6,30} This device is small and designed for intrapericardial placement, as

TABLE 29-4 INTERMACS Profiles

PROFILE DESCRIPTION	TIME FRAME FOR INTERVENTION
Profile 1: Critical Cardiogenic Shock	
Patients with life-threatening hypotension despite rapidly escalating inotropic support, with critical organ hypoperfusion, often confirmed by worsening acidosis and/or lactate levels. "Crash and burn."	Definitive intervention needed within hours
Profile 2: Progressive Decline	
Patient with declining function despite intravenous inotropic support; in a few cases, may be manifested by worsening renal function, nutritional depletion, inability to restore volume balance. "Sliding on inotropes." Also describes declining status in patients unable to tolerate inotropic therapy.	Definitive intervention needed within days
Profile 3: Stable but Inotrope-Dependent	
Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support (or a temporary circulatory support device or both), but demonstrating repeated failure to wean from support owing to recurrent symptomatic hypotension or renal dysfunction. "Dependent stability."	Definitive intervention elective over a period of weeks to few months
Profile 4: Resting Symptoms	
Patient can be stabilized close to normal volume status but experiences daily symptoms of congestion at rest or during ADL. Doses of diuretics generally fluctuate at very high levels. More intensive management and surveillance strategies should be considered, which may in some cases reveal poor compliance that would compromise outcomes with any therapy. Some patients may shuttle between levels 4 and 5.	Definitive intervention elective over period of weeks to few months
Profile 5: Exertion Intolerant	
Comfortable at rest and with ADL but unable to engage in any other activity, living predominantly within the house. Patients are comfortable at rest without congestive symptoms but may have underlying refractory elevated volume status, often with renal dysfunction. If underlying nutritional status and organ function are marginal, patient may be more at risk than in profile 4 and require definitive intervention.	Variable urgency; depends on maintenance of nutrition, organ function, and activity
Profile 6: Exertion Limited	
Patient without evidence of fluid overload is comfortable at rest, and with ADL and minor activities outside the home but fatigues after the first few minutes of any meaningful activity. Attribution to cardiac limitation requires careful measurement of peak oxygen consumption, in some cases with hemodynamic monitoring to confirm severity of cardiac impairment. "Walking wounded."	Variable urgency; depends on maintenance of nutrition, organ function, and activity level
Profile 7: Advanced NYHA Class III	
A placeholder for more precise specification in future, this level includes patients who are without current or recent episodes of unstable fluid balance, living comfortably with meaningful activity limited to mild physical exertion.	Transplantation or circulatory support may not currently be indicated

ADL = activities of daily living.

with the HVAD. The device incorporates a bearingless design with complete magnetic levitation of the impeller. The MVAD is a small, implantable continuous flow rotary pump with axial design.^{6,29} The pump uses hydromagnetic levitation of the impeller that eliminates the need for an internal bearing for impeller support. The small size of the pump facilitates applications to minimally invasive surgical implantation, biventricular support applications, and different inflow and outflow configurations.²⁹

The percutaneous lead has been a significant source of morbidity and adversely influences quality of life for patients on MCS support.³¹ The introduction of wireless energy transfer will allow MCS systems to receive energy transcutaneously without the need for the percutaneous lead.³² The entire MCS system will be implantable, with an internal power source permitting short periods of support allowing the patient to pursue activities such as swimming or bathing, which are restricted with current technology. The incorporation of this type of technology, if successful, can be expected to increase patient satisfaction and quality of life significantly.

To date, a majority of MCS devices have been designed to provide complete cardiac output or full support. As MCS therapy moves into populations of patients with less advanced heart failure, the concept of small, partial-assist MCS devices has been developed to reverse heart failure symptoms with only limited assist of cardiac function.³³ These systems include the Synergy (HeartWare Inc., Framingham, Mass) (Fig. e29-9) and the C-Pulse (Sunshine Heart, Eden Prairie, Minn).³⁴ The Synergy is a small, implantable continuous flow rotary

pump with axial design utilizing bearing support of the internal impeller. The device is intended for long-term MCS. The inflow cannula of the device is attached to the left atrium using a right thoracotomy approach. The outflow graft is attached to the right subclavian artery. The pump is implanted in a small subcutaneous pocket in the right chest wall. The Synergy is not commercially available. The C-Pulse is a counterpulsation device similar in concept to the IABP but is implanted around the ascending aorta, rather than being placed into the circulation.³⁴ The major feature of the device is the reduction in potential risk of stroke, because the device is not incorporated into the circulation and can be turned on and off without risk of device thrombosis.

Important developments in the pediatric field include the PumpKIN Trial (Pumps in Kids, Infants and Neonates).³⁵ PumpKIN is an NHLBI initiative to investigate the use of several novel pump designs and ECLS systems for pediatric MCS application. The trial is investigating two unique miniaturized ECLS systems and an implantable pump design based on the Jarvik 2000 VAD.³⁵ The initiative is a collaboration among industry, clinical centers, and the New England Research Institutes (NERI), designated as the data coordinating center for the trial. Two national registries will serve as contemporary observational control arms for the new devices studied in PumpKIN. PediMACS, an INTERMACS initiative dedicated to pediatric patients, will serve as the contemporary observational arm for the PumpKIN trial using the FDA-approved pediatric device, Berlin Heart Excor Pediatric VAD (Berlin Heart, GmbH Berlin). Data for the MCS devices designed for

ECLS in the PumpKIN trial will be compared against contemporaneous outcomes for ECLS in the Extracorporeal Life Support Organization (ELSO) registry.

The introduction of safer, smaller, and more durable LVADs has significantly increased the adoption of LVAD therapy for DT in the treatment of advanced heart failure.²⁸ The broader application of LVAD therapy has been associated with a shift toward implantation in patients with less advanced stages of heart failure. However, the minimum reduction in risk from heart failure mortality and morbidity that is necessary for a patient to experience survival, quality of life, or functional improvement from VAD therapy for DT is unknown. The Randomized Evaluation of VAD Intervention Before Inotropic Therapy (REVIVE-IT) Pilot Trial (ClinicalTrials.gov Identifier: NCT01369407)³⁶ is a prospective, randomized controlled trial sponsored by the National Institutes of Health (NIH) that will investigate the use of VAD therapy in a less-ill cohort of patients with advanced heart failure (<http://clinicaltrials.gov/show/NCT01369407>). Trial subjects will be assigned in random fashion to either LVAD therapy with the HeartMate II LVAD or OMM. The hypothesis of the study is that LVAD implantation in patients with less advanced symptoms of heart failure will achieve superior outcomes owing to the reduction in adverse events typically associated with treatment of patients with very advanced and late stages of heart failure.

Widespread interest in MCS therapies has resulted in global adoption and clinical application of this technology. An understanding of international outcomes based on uniform definitions of outcomes and adverse events is essential to the sustainability of MCS therapy and to foster efficient device development and clinical evaluation. IMACS is an international registry collaboration supported by the International Society of Heart and Lung Transplantation and INTERMACS that was initiated to achieve international cooperation on reporting of MCS outcomes.³⁷ Efforts to create uniform registration and reporting requirements worldwide constitute an important initiative of the FDA to facilitate clinical device evaluation in the United States.³⁸

ENGINEERING DESIGNS OF VENTRICULAR ASSIST DEVICES

General Characteristics

VADs have in common a number of basic components despite the differences in design and indications for use. All systems for left-sided support (arterial system), whether temporary or designed for long-term use, consist of an inflow cannula that drains blood from the heart (most commonly directly from the LV apex or from the left atrium via the right superior pulmonary vein or transseptal approach) to the pump and an outflow cannula that carries blood back to the arterial system by way of the aorta or femoral, axillary, or carotid artery, depending on the particular MCS device. For RV support systems, cannulas usually are positioned to drain blood from the right atrium (most common) or right ventricle and return blood to the pulmonary artery. Temporary devices typically have long cannulas that attach to the heart, traverse the skin, and then connect to the pump. Although the actual pump may reside in the body, as with the Impella device (Abiomed, Inc., Danvers, Mass) (**Fig. e29-2**), the motor to drive the pump for temporary MCS devices is located outside the body (in an extracorporeal position) (see **Fig. e29-1**). Long-term, implantable MCS devices generally are designed with very short inflow cannulas, as with the HeartMate II (Thoratec) (see **Fig. e29-2**) have incorporated the inflow cannula into the pump as in the HeartWare HVAD

(HeartWare) (**Fig. 20-3**), or, as with the Jarvik 2000 (Jarvik Heart, Inc., New York) (**Fig. 29-4**), have eliminated the inflow cannula entirely and placed the pump within the left ventricle. The power supply for implantable pumps is delivered through a percutaneous lead that traverses the skin and connects the external power system with the internal pump (see **Fig. 29-1**). The external components of an implantable system generally consist of a power source (i.e., batteries or an alternating current power unit) and a small portable computer (controller) that controls device speed and monitors device function.

Pulsatile, Volume Displacement Pumps

Early MCS devices, typically referred to as first-generation devices, were based on a volume displacement design with pulsatile flow that mimicked the phasic contractions of the human heart. Pulsatile, volume displacement designs are now largely limited to paracorporeal systems for BTR or BTT indication. Pulsatile flow systems remaining in clinical use in the United States and internationally represent paracorporeal systems such as the Abiomed AB 5000 (Abiomed) (not shown), Thoratec pVAD (Thoratec) (see **Fig. e29-2**) or Berlin Excor (Berlin Heart) (not shown). The last-remaining pulsatile, implantable system in clinical use in the United States is the Thoratec IVAD (Thoratec) (see **Fig. e29-3**), which remains the only implantable VAD system available for long-term biventricular support. The major feature of these pulsatile, paracorporeal or implantable pulsatile systems that contributes to their continued use is the flexibility to provide biventricular support. Today, the use of pulsatile pumps is largely restricted to temporary MCS support as extracorporeal pumps for BTR or as paracorporeal pumps for BTT indication in patients who do not have other options for implantable, durable pumps. Paracorporeal systems are not approved for the DT indication. All early implantable pulsatile pumps approved for BTT or DT indication, such as the HeartMate XVE (Thoratec) (not shown) and Novacor (WorldHeart, Salt Lake City, Utah) (not shown), are of historical interest only, because they are no longer manufactured.

Continuous Flow Rotary Pumps

The field of MCS has significantly evolved from volume displacement pulsatile pumps to continuous flow rotary pumps. This trend has continued for both short- and long-term MCS device designs. Continuous flow rotary pumps offer several advantages over pulsatile, volume displacement pumps. These advantages include smaller size, fewer moving parts (resulting in greater durability and reliability), limited blood contacting surfaces, and reduced energy requirements.

A continuous flow pump consists of blood inlet and outlet ports and a single rotating impeller suspended within a tube that propels blood forward by spinning the internal impeller at high

FIGURE e29-2 A, Thoratec pVAD is a pneumatically actuated VAD designed for right-sided, left-sided, or biventricular support. B, Thoratec pVAD in LV assist (left side) and biventricular assist (right side) configurations. (Reprinted with permission of Thoratec Corporation.)

FIGURE e29-3 Thoratec intracorporeal VAD (IVAD) (lower device) beside the Thoratec pVAD. The Thoratec IVAD is an implantable version of the Thoratec pVAD. (Reprinted with permission of Thoratec Corporation.)

speeds, thereby imparting significant kinetic energy to the blood (Fig. e29-4). The spinning of the impeller is accomplished by actuating an electrical current and magnetic field around the impeller, which contains internal magnets. Although continuous flow through the pump occurs throughout the cardiac cycle, there are also superimposed phasic changes in pump flow also. Pump flow is greater during native cardiac systole than during native cardiac diastole because native LV contraction raises intracardiac pressure, thereby lowering the pressure gradient (the difference between aortic and LV pressures) the pump must overcome to generate forward flow (Fig. e29-5). These phasic changes in blood flow with a rotary pump impart a pulse to the native circulation. The magnitude of pulse pressure typically is diminished compared with that generated with a native heart contraction or pulsatile flow pump. Under normal circumstances (pump working in conjunction with the native heart contraction), the aortic flow pattern with a rotary pump is more accurately described as being continuous, rather than using the description of nonpulsatile flow. In circumstances in which there is absence of native heart contraction (e.g., ventricular fibrillation), the flow through a continuous flow rotary pump is nonpulsatile.

Other important distinguishing characteristics of continuous flow pumps are the flow pattern and the mechanism of impeller support

(see Fig. e29-4).^{1,2} A distinguishing feature of continuous flow pumps is the method by which the internal impeller is supported. The internal impeller in axial or centrifugal designs may or may not be supported by mechanical bearings (mechanical pivot design). Continuous flow pump designs incorporating a bearing for impeller support have traditionally been referred to as second-generation pumps.^{1,2} A more advanced bearingless design in which the internal impeller is suspended in the blood path by active or passive magnetic forces or hydrodynamic forces is referred to as a third-generation pump design. Levitation systems utilized in third-generation rotary pumps suspend the moving impeller within the blood field without any mechanical contact. Magnetic forces may be passive without the consumption of power (permanent magnet) or active (induction of magnetic field with electricity) in design. Hydrodynamic levitation depends on fluid forces generated by the rotating impeller to levitate the internal impeller. Pump designs can be further distinguished by the utilization of hydrodynamic levitation only, hydrodynamic levitation working in synergy with magnetic levitation for suspension, or variations of active and/or passive magnetic levitation. Active magnetic levitation of the impeller typically uses complex position sensing and control systems that increase requirements for a larger pump size. Hydrodynamic suspension does not utilize position sensors resulting

FIGURE e29-4 **A**, An example of a second-generation continuous flow rotary pump with axial flow design. The internal impeller is supported by outflow and inflow stators (mechanical pivot design) with bearings. The internal impeller contains a magnet. Rotation of the impeller is achieved by an alternating magnetic field generated from the motor and electrical coils surrounding the impeller. **B**, An example of a third-generation continuous flow rotary pump with centrifugal design. Internal impeller supported by magnetic levitation. Bearings are eliminated. The impeller rotation is achieved by motor stators that are magnetically coupled to the impeller. Schematic diagram demonstrates the blood flow path from the inflow section (a), blood flow path through the impeller and the backflow paths above the shroud and between the rotor and the motor (b), and outflow path (c). (From Farrar DJ, Bourque K, Dague CP, et al: Design features, developmental status, and experimental results with the Heartmate III centrifugal LV assist system with a magnetically levitated rotor. *ASAIO J* 53:310, 2007.)

FIGURE e29-5 Flow pattern of a continuous flow rotary pump. The flow of blood in a continuous flow rotary pump is both continuous during the entire cardiac cycle and phasic (more flow through the pump is observed during native cardiac systole than during native cardiac diastole as a result of the interaction of the native heart contraction and hydrodynamic properties of the pump). These phasic changes in blood flow with a rotary pump are caused by a change in pressure gradients across the pump consequent to changes in native diastolic and systolic pressures. During diastole, the pressure gradient across the pump (the difference between aortic [P_{aorta}] and LV [P_{LV}] pressures) is greatest, resulting in less flow. During systole, the pressure gradient across the pump (the difference between P_{aorta} and P_{LV}) is less, resulting in more flow. These pressure changes induce corresponding changes in flow that impart a pulse to the native circulation.

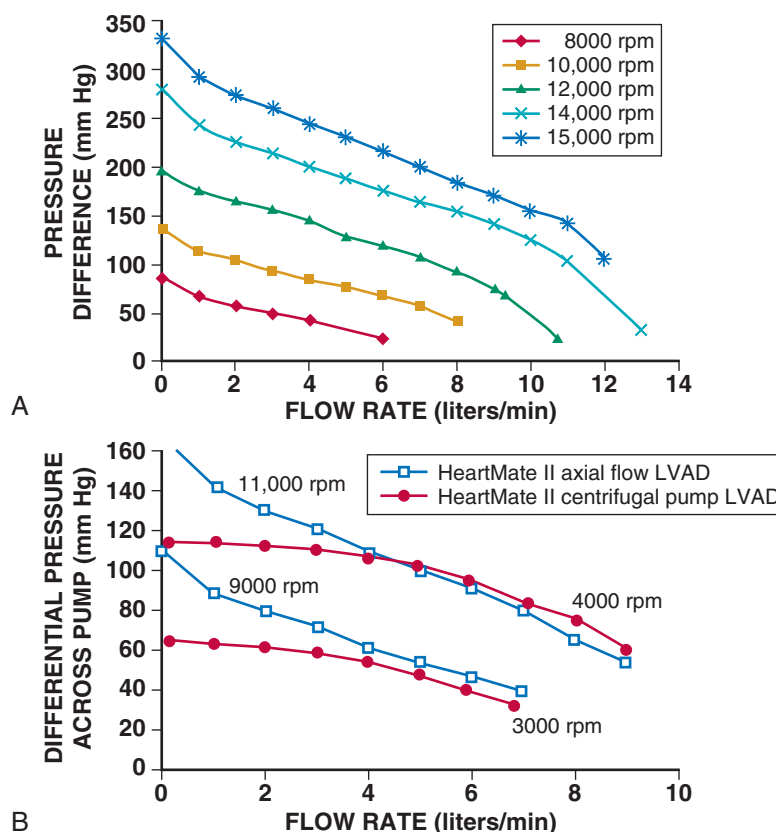

FIGURE e29-6 Hydrodynamic properties of a continuous flow rotary pump. **A**, Blood flow through a continuous flow rotary pump is inversely related to pressure gradient (the difference between aortic and LV pressures) across the pump and directly related to pump speed. This pressure-flow relationship is visualized by series of pressure-flow curves at different pump speeds. **B**, The pressure-flow relationship for an axial flow pump is steeper than that for a centrifugal flow pump. The less steep pressure-flow relationship of a centrifugal pump elicits greater variation in pump flows during the cardiac cycle—that is, smaller changes in pressure result in larger changes in pump flow.

in a less complicated electronic design and ability to miniaturize pump size. However, in circumstances of low rotational speeds or if the pump were to stop, hydrodynamic forces may be inadequate to prevent the impeller from coming into contact with the outer device housing, potentially causing impeller damage or heat generation leading to thrombus formation.

There are theoretical benefits to incorporation of a bearingless design into the third-generation pumps. The bearings present in the blood path that suspend the impeller in second-generation pumps constitute a potential point of frictional wear and of heat generation. Frictional wear of the bearing may potentially result in device failure and subsequent need for device exchange. Bearings also may represent a potential site for thrombus formation at the interface of the impeller and bearing if the bearing design does not permit adequate blood “washing” of the bearing surfaces and create localized areas of blood stasis. Heat generated by the contact of the impeller and bearing is dissipated by blood flow through the pump. Periods of low flow through a pump can result in inadequate heat transfer from the bearing and result in denaturation and deposition of proteins on the bearing. This deposition could contribute to future thrombus formation or hemolysis. Additionally, the presence of stators that support the bearings and act to redirect blood flow in second-generation pumps also represents an obstruction within the blood flow path and a potential site for thrombus deposition.

Blood flow through continuous flow pumps, both axial and centrifugal, is directly proportional to pump speed and inversely related to the pressure difference across the inlet (LV pressure) and outlet (aortic pressure) orifices of the pump. Centrifugal devices are more

efficient at energy transfer and provide continuous flow at rotational speeds that are much slower, approximately 2000 to 4000 rpm compared with 8000 to 15,000 rpm for pumps with axial flow designs.^{1,2} The relationship between pressure and flow can be displayed in a series of curves reflecting blood flow over varying pressure gradients at specific pump speeds; pressure-flow relationship (Fig. e29-6). The relationship between flow and pressure with axial pumps differs from that of centrifugal pumps. With centrifugal blood pumps, the pressure-flow relationship tends to be less steep, such that small changes in pressure across a centrifugal pump produce larger changes in blood flow compared with those occurring with an axial pump (see Fig. e29-6). The more responsive pressure-flow relationship in centrifugal pumps results in a greater degree of flow variability across the cardiac cycle (less flow in diastole and more flow in systole). In theory, the benefits of centrifugal versus axial pumps are a greater aortic pulse pressure and less propensity to create LV collapse or a “suction event” resulting from the greater drop in pump flow as LV end-diastolic pressures decrease. LV collapse or “suction” events elicited by a VAD may cause ventricular arrhythmias or increase the propensity for thrombus formation on bearings as a result of low flow or on the endocardium owing to trauma.

IMPORTANT MEDICAL CONDITIONS IN INSTITUTING MECHANICAL CIRCULATORY SUPPORT

Valvular Heart Disease

Abnormalities of the cardiac valves have important adverse consequences in patients being considered for MCS and may require repair or replacement in order to initiate successful MCS or achieve weaning from support. Mild to moderate aortic stenosis in the absence of insufficiency is not a contraindication to placement of a VAD. Severe aortic stenosis should be corrected prior to placement of a VAD, preferably with a bioprosthetic valve, to facilitate future weaning or optimize native heart function in the event of device failure. The presence of moderate aortic insufficiency can have a significant impact on the effectiveness of MCS therapy. In cases in which LV assistance is initiated with left atrial-to-aortic cannulation, aortic insufficiency will result in LV distention in the presence of significant LV dysfunction. LV distention adversely affects subendocardial blood flow and can prevent weaning from MCS. In cases in which MCS support is initiated with devices that require LV apical-to-aortic cannulation, reductions in LV pressure elicited by MCS increase the pressure gradient across the aortic valve and increase the degree of aortic insufficiency. Blood pumped into the aorta by the LVAD will flow backward across the incompetent aortic valve (aortic insufficiency), decreasing net forward flow and compromising end-organ perfusion. Mild to moderate aortic insufficiency may become more severe with initiation of MCS from an LVAD because the elevated LV end-diastolic pressure will be significantly reduced by emptying of the LV cavity by the device and the aortic root pressure will be elevated above baseline because of device flow. The presence of significant aortic insufficiency can be confirmed by echocardiography. Patients with a mechanical valve prosthesis in the aortic valve position should have the mechanical valve replaced with a bioprosthetic valve before institution of LV assistance. During complete unloading of the left ventricle by a VAD, the aortic valve may not open and the mechanical valve may be prone to thrombus formation. Placing a patch over the mechanical valve may be another alternative but may increase thromboembolic risk.

Patients with significant mitral stenosis at the time of initiation of device support may require correction of the valvular problem before implantation of a device depending on device selection and site of cannulation. In the setting of significant mitral stenosis, LV filling is impaired. VADs that utilize apical ventriculotomy for cannula placement for ventricular drainage may experience limitations in device filling resulting from mitral stenosis. This problem can be circumvented either by choosing a device that can use left atrial drainage or by correcting the underlying valvular pathologic abnormality (mitral valve repair or replacement with a bioprosthetic valve). The impact of mitral regurgitation on limiting forward flow through a VAD is not well understood, and data to suggest routine repair or replacement of the mitral valve for insufficiency are lacking. However, in situations in which weaning from MCS may be feasible, correction of the mitral pathologic condition, either stenosis or regurgitation, is necessary to optimize ventricular function.

Adequate RV function is extremely important for maintaining LVAD flow in the early postoperative period. Severe tricuspid regurgitation can significantly impair the forward flow of blood from the right ventricle, particularly in the setting of abnormalities of high pulmonary vascular resistance. Severe tricuspid regurgitation contributes to elevated central venous pressure, hepatic congestion, and renal dysfunction. Severe tricuspid regurgitation may be present preoperatively in the setting of volume overload and biventricular failure or may develop after institution of LVAD support as a consequence of RV dilation from leftward shift of the interventricular septum.^{1,3} If severe tricuspid regurgitation is present during the initiation of LVAD

support, tricuspid valve repair should be performed to improve RV performance.

Coronary Artery Disease

Patients with significant obstructive coronary artery disease or patients with postcardiotomy shock following failed coronary bypass operations may experience angina during MCS. Generally, coronary artery disease does not have adverse hemodynamic consequences during the period of MCS. However, the presence of obstructive coronary disease with ongoing ischemia may limit the degree of myocardial recovery and affect the ability to wean from temporary MCS.

Perioperative ischemia of the right ventricle may be of hemodynamic significance during institution of LVAD support. RV ischemia causing myocardial stunning or infarction that occurs during or soon after implantation of an LVAD can elicit RV failure, resulting in decreased flow to the LVAD. In patients who have had coronary bypass surgery and are candidates for MCS, patent bypass grafts, particularly to the right coronary artery or left anterior descending coronary artery should be preserved in order to reduce the risk of perioperative RV failure and arrhythmias. In selected situations it may be important to perform a coronary artery bypass to the right coronary artery or left anterior descending coronary artery systems to optimize RV function in the perioperative period if significant obstructive coronary lesions amenable to bypass are present in the distribution of these arteries.

Arrhythmias

Atrial and ventricular arrhythmias are common in patients with cardiogenic shock and underlying ischemic or idiopathic cardiomyopathies. These arrhythmias generally persist in the immediate postoperative period and subsequently resolve with time as the hemodynamic condition of the patient improves and inotropic therapy is weaned. Some patients will have persistent arrhythmias as a result of their underlying pathology (e.g., giant cell myocarditis). Severe ventricular arrhythmias have traditionally been thought to be a contraindication to univentricular support. However, the hemodynamic consequences in patients in whom these arrhythmias develop in the late postoperative period generally are not life-threatening. In the absence of pulmonary hypertension and elevated pulmonary vascular resistance in the postoperative period, patients maintain adequate LVAD flows during ventricular fibrillation. This situation is analogous to a Fontan (systemic vein to pulmonary artery) circulation. In the early perioperative period, some patients with refractory ventricular arrhythmias may require biventricular support until the pulmonary vasculature resistance drops and a Fontan circulation is tolerated. The addition of RV support for hemodynamic compromise owing to refractory ventricular arrhythmia is unusual. In situations in which weaning from MCS is feasible or planned, elimination of the ventricular arrhythmias with antiarrhythmic therapy is essential.

Intracardiac Shunts

Intracardiac shunts such as a patent foramen ovale or atrial septal defect should be closed at the time of implantation of an LVAD to prevent right-to-left shunting. These anomalies should be identified before surgery using transesophageal echocardiography. During the initiation of LV assistance, left atrial pressure is reduced compared with right atrial pressure. In the presence of an atrial septal defect or patent foramen ovale, this gradient results in significant systemic hypoxemia as deoxygenated blood is shunted from the right to left atrium.

CLINICAL TRIALS WITH THE HEARTMATE II DEVICE

The HeartMate II Pivotal Trial for BTT was an FDA-approved, prospective, nonrandomized, multicenter study of 133 patients with end-stage heart failure who were on a waiting list for heart transplantation and received implantation of the HeartMate II device (see Table 29-3). The primary endpoint was a composite of the proportions of patients who, at 180 days, had undergone transplantation, were explanted for cardiac recovery, or had ongoing MCS with the HeartMate II while remaining eligible for transplantation. Of the 133 patients receiving support with the HeartMate II device, the principal outcomes were observed in 100 patients (75%).¹ At 3 and 6 months, device support with the HeartMate II was associated with significant improvement in functional status (NYHA functional class and 6-minute walk test distance) and in quality of life (Minnesota Living with Heart Failure and Kansas City Cardiomyopathy questionnaires).¹ Major adverse events included postoperative bleeding, stroke, right-heart failure, percutaneous lead infection, and device malfunction (see Table e29-2). After this initial report of data for 133 patients, a follow-up evaluation was conducted through a continued access protocol (CAP) that included an additional 148 patients.² At 18 months, 222 patients (79%) met the primary endpoint, as defined previously for the pivotal trial.² The primary causes of death were sepsis, stroke, and right-heart failure. Episodes of bleeding requiring transfusion and surgery were the most common adverse events in the study, followed by stroke, localized infection not related to the device, infection associated with the percutaneous lead, preperitoneal pump pocket infection, and right-heart failure. There were no mechanical failures of the pumping mechanism. The freedom from device replacement for all causes, including infection, device thrombosis, and percutaneous lead failure, was 92% (95% CI, 88% to 97%) at 18 months.²

After completion of the FDA pivotal trial for evaluation of the HeartMate II for BTT indication, a clinical study of the HeartMate II was performed for the first 169 consecutive patients enrolled in the post-approval phase, and results were compared with those for the first 169 consecutive patients who received another FDA-approved VAD (79% HeartMate XVE, 21% Thoratec IVAD) enrolled in INTERMACS (Interagency Registry for Mechanically Assisted Circulatory Support) who were listed for transplantation or likely to be listed.³ Kaplan-Meier survival at 12 months was significantly greater for HeartMate II recipients than for control subjects ($P = .001$), and this advantage was sustained after adjustment for significant baseline differences in creatinine, blood urea nitrogen, white blood cell count, heart rate, pump type, and aspartate transaminase (AST) ($P = .009$). A greater percentage of patients in the HeartMate II (90%; $n = 152$) versus the control (80%; $n = 130$) group reached the successful outcomes of survival to transplant, recovery of the heart, or ongoing support at 6 months ($P = .018$).

The HeartMate II DT Pivotal Trial randomly assigned 200 patients with NYHA class III/IV symptoms and a LVEF $\leq 25\%$, to receive a

HeartMate II or a HeartMate XVE.⁴ Eligible patients also had to have either a maximal oxygen consumption not exceeding 14 mL/kg/min, require treatment with intravenous inotropic agents for 14 days or longer, or an intra-aortic balloon pump for 7 days or longer.⁴ The primary endpoint was a composite of survival to 24 months without disabling stroke or the need for an operation to repair or replace the device. The patient population was predominately male, with a mean age of 62 years. This was a severely ill population as reflected by a mean LVEF of 17% and mean creatinine 1.6, relatively low use of baseline neurohormonal antagonists and substantial use of inotropes (77%) and intra-aortic balloon pumps (22%). There was a greater than fourfold increase in the percentage of HeartMate II patients who successfully reached the primary endpoint (46% versus 11%; $P < .001$).⁵ (see Table 29-3) All adverse events were less frequent in the HeartMate II patients, with significant reductions in sepsis, device-related infections, right-heart failure, renal failure and rehospitalizations. Changes in functional capacity, 6-minute walk distance, and quality of life scores were similar between groups, suggesting that the improvements seen in these metrics in VAD-supported patients are more closely linked to the favorable effects of increasing the cardiac output and lowering the left-sided filling pressures rather than the characteristics of blood flow. The favorable results of the HeartMate II DT Pivotal Trial resulted in FDA approval of this device in 2010 as the second LVAD indicated for long-term support for DT.

A follow-up study reported the outcomes of patients entered into the HeartMate II Pivotal Trial for Destination Therapy through a CAP to those entered in the original cohort to determine if outcomes in the latter group were superior to those in the former group.⁶ Two hundred eighty-one patients who underwent HeartMate II for DT from May 2007 to March 2009 (Mid-Trial group) were compared with the initial 133 HeartMate II patients from March 2005–May 2007 (Early Trial group). Patient entry criteria were the same and important baseline characteristics were similar for the two groups. Kaplan Meier survival for the Early Trial and Mid-Trial experiences are displayed in Table 29-3.⁶ There were nominal improvements in survival, quality of life, and many adverse events, some of which achieved statistical significance (see Table 29-4).

A longstanding quest in cardiovascular therapeutics is to regenerate injured tissue or to correct fundamental molecular defects in signaling pathways that cause organ dysfunction in the setting of heart failure. Regardless of the specific etiologic disorder, the failing myocardium is composed of diseased cardiac myocytes, permanently lost cardiac myocytes that are replaced by fibrous tissue, and normal cardiac myocytes. As shown in **Figure 30-1**, the goal of cell therapy is to replace the permanently lost cardiac myocytes within the myocardium, whereas the goal of gene therapy is to improve the function of the failing cardiac myocytes by modulating the expression of specific genes. Significant overlap exists between gene and cell therapies. Genetically modified cells have been shown to have better survival and differentiation capacity once transplanted into the myocardium. In addition, direct differentiation of fibroblasts into myocytes using gene therapy has been shown experimentally, and expression of secreted factors that induce homing of progenitor cells can be achieved by myocardial gene therapy. After decades of research, the feasibility of both of these strategies is supported by clinical and translational data.

At present, both cell and gene therapies are experimental approaches to treating heart disease. Although few late-stage clinical trials have been completed, much progress has been made in terms of delivery strategies and patient selection profiles that will shape the ultimate clinical application of cell and gene therapy in cardiovascular medicine.

CELL THERAPY

Principles of Cell- and Gene-Based Cardiac Regenerative Therapies

On first principles, the goal of cardiac cell-based therapy is to repopulate areas of damaged myocardium with cells capable of engraftment and trilineage differentiation into cardiac myocytes, vascular smooth muscle, and endothelium, whereas the goal of gene therapy is to alter gene expression within the myocardium to enhance cardiac function. Data from basic, preclinical, and clinical studies have established the principle that successful cell-based tissue repair results from an integrated orchestration of cellular and molecular events. Gene therapy approaches have targeted critical pathways that are altered in cardiovascular diseases. The initial clinical trials that tested cell-based therapy for heart disease used autologous whole bone marrow (AWBM), skeletal myoblasts, and mesenchymal stem cells (MSCs). A second wave of therapeutic approaches, many of which are still being investigated in ongoing studies, use cardiac stem cells (CSCs), mesenchymal precursor cells (MPCs), and cell combinations (**Table 30-1**). Clinical trials in gene therapy for cardiovascular diseases have been fewer, but with the development of novel vectors and the identification of novel targets, gene-based therapies are

being contemplated for cardiovascular diseases. Extensive development work has laid the groundwork for catheter-based transendocardial and transmyocardial stem cell injection. Together, the advancements made in the past decade make it possible to envision the widespread availability of cell-based therapy for a panoply of cardiac disorders currently considered chronic and incurable.

The concept of treating a wide range of human heart diseases with a regenerative strategy has been advanced by both basic biologic and translational research over the past decade.^{1,2} The idea that cell repopulation, if achievable, could be an effective therapeutic strategy has as its underpinning the paradigm that the human heart, unlike that of amphibians, fish, and possibly lower mammals,³ is terminally differentiated and incapable of regeneration in postnatal life (i.e., the human heart is a postmitotic organ). Of interest, a series of recent studies have shown that the human heart does possess the capacity for turnover of myocytes, although the rate of this process varies among the different studies.³⁻⁵ As described next, this endogenous regenerative capacity plays a critical role in cell-based tissue repair.

The approaches to finding an effective cell-based therapy have evolved considerably over the past decade. First, major attention has shifted from embryonic/pluripotent stem cells toward sources of adult cells that could have the capacity for cardiac tissue repair.^{6,7} Second, it is now clear that many other facets of cell-based therapy have the potential to contribute to the success of the approach, and these include antifibrotic effects, neovascularization, and the stimulation of endogenous CSCs.⁸⁻¹² Finally, attention has been paid to advancing the practical aspects of cell delivery through the development of effective cell delivery systems and advances in cell production; effective delivery is likely to play a pivotal role in successful translation of this new strategy.^{6,12} Gene and vector delivery systems also have evolved considerably since the first gene therapy trial for the treatment of monogenic diseases. The molecular targets for therapeutic intervention also have increased significantly over the past 2 decades for specific aspects or elements of cardiac pathophysiology. The potential of novel gene transfer technology and the demands imposed by the cardiac pathophysiology of interest are discussed in this chapter.

Cell Types Used—Past, Present, and Future Strategies

First-Generation Cell Therapeutics

Autologous Whole Bone Marrow Cells

Immediately after publication of the seminal report in 2001 by Orlic and co-workers that murine bone marrow c-kit-positive cells could repair the infarcted murine heart,¹³ a wave of clinical trials ensued to test the hypothesis that AWBM could improve the structure and function of the post-myocardial infarction (MI) heart.⁹ The totality of

FIGURE 30-1 After injury to the heart, the damaged myocardium consists of dysfunctional cardiac myocytes, dying myocytes, and normal myocytes. In addition, it becomes populated with vessels, fibroblasts, extracellular matrix, and progenitor cells, which can give rise to new cardiac myocytes. Whereas the goal of cell therapy is to replace the dying cardiomyocytes, gene therapy targets the dysfunctional cardiac myocytes. AAV = adeno-associated virus.

evidence from these trials suggests that intracoronary AWBM administered to patients after MI increased left ventricular ejection fraction (LVEF) by 2% to 3%, in an effect that increased with greater degrees of LVEF decline after infarction.^{14,15} The relatively small impact on ejection fraction, coupled with the concern over whether bone marrow–derived cells can effectively differentiate into cardiac myocytes, promoted a quest for additional cell types. Despite the fact that data for myocyte differentiation are lacking, analyses from clinical trials suggest that intracoronary AWBM can have clinical benefits, reducing heart failure hospitalization and reinfarction rates.¹⁶ As a result, the merit of AWBM as a clinical therapy will be subjected to a pivotal phase III study, the Effect of Intracoronary Reinfusion of Bone Marrow–Derived Mononuclear Cells (BM-MNC) on All-Cause Mortality in Acute Myocardial Infarction (BAMI) trial (NCT01569178). For this 3000-patient, randomized phase III trial, conducted in Europe, mortality is the primary outcome variable (see Table 30-1).

Mesenchymal Stem Cells

Another notable strategy undergoing early-stage clinical testing is the use of MSCs. These adult stem cells are prototypically found in the bone marrow, from which they can be cultured. MSCs are niche-regulating cells, widely distributed in adipose tissue, umbilical cord blood, endometrium, and other sources,¹ that have the capacity for multipotent differentiation and neovascularization. MSCs have been tested in phase I trials for treatment of acute MI,¹⁷ proof-of-concept studies for treatment of ischemic heart failure,⁶ and phase I and phase II clinical trials for treatment of heart failure due to ischemic and nonischemic cardiomyopathy and acute MI. MSCs are particularly attractive as a cell therapeutic, because they are immunoprivileged (Fig. 30-2) and therefore have potential as an “off the shelf” therapeutic.⁹ In a study conducted in patients with chronic ischemic cardiomyopathy that compared allogeneic and autologous bone marrow–derived MSCs, the immunologic profile of the MSCs was acceptable, and both types of cells had similar efficacy (Fig. 30-3). In two studies, MSCs (both allogeneic and autologous) reduced MI size by ~33%, improved indices of myocardial remodeling, and improved patient quality of life and functional capacity.^{18,19}

In addition to bone marrow–derived cells, MSCs derived from alternative tissue sources, notably fat, also are currently under evaluation for use as cardiac therapeutics.²⁰ The use of adipose-derived MSCs is

advantaged by the abundance of these stem cells in adipose tissue, allowing isolation of adequate numbers of cells without requiring expansion.

Skeletal Myoblasts

Skeletal myoblasts represent a third cell type that has undergone clinical testing. After completion of several early-stage trials suggesting benefit, a phase II investigation involving the random assignment of 97 patients to specific treatments failed to show significant clinical benefit. Thus the approach of using autologous skeletal myoblasts has an uncertain future.

Endothelial Precursor Cells (CD34⁺ Cells)

Another application of cell-based therapy has entailed a neo-angiogenesis strategy using CD34⁺ endothelial precursor cells in patients with chronic angina pectoris and acute MI.^{21,22} This strategy is based on the idea that these cells can generate microvasculature in poorly perfused tissue sections. Abundant support for this hypothesis has accrued, and a recent phase II trial provides insights into the possibility of clinical efficacy.²³ The success of the phase II trial of CD34⁺ cells has paved the way for

an ongoing phase III study that will test the clinical impact of this form of cell therapy (see Table 30-1).

Second-Generation Cell Therapeutics

The field of cell-based therapy is rapidly advancing with regard to the quest for more effective cell products, and numerous strategies are now entering proof-of-concept early-stage clinical investigations. An approach to advancing MSC strategies involves identifying an MSC precursor cell in a tissue source, usually the bone marrow. In addition to culturing MSCs, MPCs can be obtained through epitope-based cell enrichment techniques, including the use of Stro-1, Stro-3,²⁴ and potentially CD271. Other second-generation MSC-related cells include multipotent adult precursor cells (MAPCs)^{25,26} and cardiopoietic MSCs.²⁷ Whereas MAPCs are MSC-like cells that are more primitive and therefore are theorized to have a greater differentiation capacity, cardiopoietic MSCs are MSCs that are cultured with a cocktail of cardiopoietic cytokines shown to enhance the ability of the MSC to differentiate in vitro and in vivo. With regard to clinical testing, Stro-3 MPCs and MAPCs are each in phase II testing for a variety of indications, including ischemic heart failure and/or acute MI (see Table 30-1). In the recently completed C-CURE trial of cardiopoietic MSCs, intramyocardial administration of these autologous cells increased ejection fraction, reduced end-systolic volume, and improved both the 6-minute walk distance and a clinical composite score.²⁷

Cardiac Stem Cells

One of the most exciting and transformative discoveries of the past decade is that of the adult CSC.²⁸ A compartment of stem cells capable of trilineage differentiation has been described in the mammalian heart that bears the c-kit receptor.²⁸ These cells exist in niches, akin to niches found in other organ systems (Fig. e30-1). Other CSCs are defined by expression of the Isl-1 transcription factor (found in the fetal heart—probably a second heart field precursor), the Sca-1 receptor (found in lower mammals without a human analogue), cells expressing the WT1 transcription factor, which are described to be in the subepicardium.^{30,31} Of these cells, c-Kit positive CSCs are the best characterized and have entered early-stage clinical testing. A pure preparation of CSCs, amplified from autologous atrial appendage samples, was tested for clinical safety in the Cardiac Stem

FIGURE e30-1 Human cardiac stem cell (CSC) niche. **A**, C-kit-positive (green) CSCs are nested together in the myocardial interstitium and are surrounded by fibronectin (Fn) (bright blue). These human CSCs are connected by gap junctions represented by connexin 43 (Cx43) (yellow dots), and adherens junctions shown by N-cadherin (N-cadh) (magenta) to cardiomyocytes (α -sarcomeric actin [α -SA]) (red). **B**, The outlined rectangular area in **A** at higher magnification. The cell-to-cell communications between CSCs and cardiomyocytes are indicated by arrowheads. Additionally, Cx43 is detected between CSCs. **C**, Nichelike structures can be reconstituted in injured myocardium. MSCs when injected not only differentiate into vascular structures and myocytes but also form clusters of cells wherein they join with endogenous cardiac stem cells. DAPI = 4',6-diamidino-2-phenylindole; GFP = green fluorescence protein. (**A**, **B**, From Leri A, Anversa P: Stem cells and myocardial regeneration: cooperation wins over competition. *Circulation* 127:165, 2013; **C**, from Hatzistergos KE, Quevedo H, Oskouei BN, et al: Bone marrow mesenchymal stem cells stimulate cardiac stem cell proliferation and differentiation. *Circ Res* 107:913, 2010.)

TABLE 30-1 Ongoing or Recently Completed Clinical Trials of Cell Therapy For Cardiovascular Disease (Phases II and III)

TRIAL	PHASE	CELL TYPE	INDICATION	STATUS
Osiris NCT00877903	Phase II	Allogeneic MSC	Acute MI	Enrollment comp
C-CURE NCT00810238	Phase II	Cardiopoietic MSC	Ischemic CMP	Enrollment comp
Mesoblast NCT01781390	Phase II	Mesenchymal precursor cell	Ischemic CMP	Initiating
TAC-HFT NCT00768066	Phase I/II	Autologous MSC	Ischemic CMP	Enrollment comp
POSEIDON-DCM NCT01392625	Phase I/II	Autologous vs allogeneic MSCs	Dilated CMP	Enrolling
BAMI NCT01569178	Phase III	AWBM	Acute MI	Initiating
CD34 NCT01508910	Phase III	CD34 ⁺ EPCs	Angina pectoris	Active

AWBM = autologous whole bone marrow; CMP = cardiomyopathy; comp = complete; EPC = endothelial precursor cell; MSC = mesenchymal stem cell.

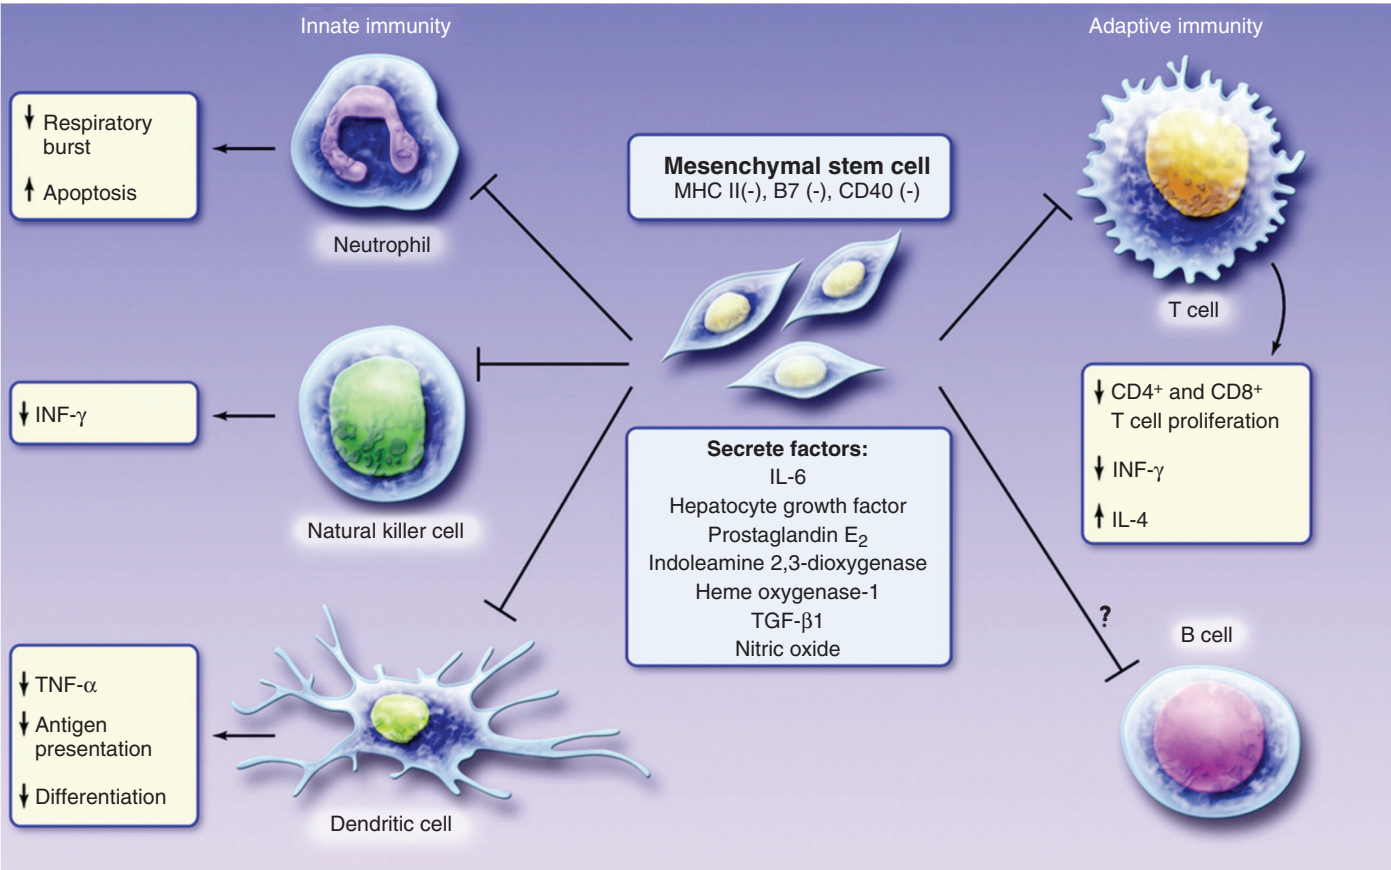

FIGURE 30-2 MSC interactions with immune cells. MSCs are immunoprivileged cells that inhibit both innate (neutrophils, dendritic cells, natural killer cells) and adaptive (T cells and B cells) immune cells. IL-4, IL-6 = interleukins 4, 6; INF = interferon; MHC = major histocompatibility complex; TGF = transforming growth factor; TNF = tumor necrosis factor. (From Williams A, Hare JM: Mesenchymal stem cells: biology, pathophysiology, translational findings, and therapeutic implications for cardiovascular disease. *Circ Res* 109:923, 2011.)

Cell Infusion in Patients with Ischemic Cardiomyopathy (SCIPIO) trial.^{32,33} Intracoronary infusion of autologous cardiac c-Kit cells resulted in an increase in ejection fraction and a decrease in infarct size, both of which were sustained over a 2-year period (Fig. 30-4).⁷ Advances in the biology of CSCs have led to further characterization of c-kit-positive CSCs. Recently it was identified that c-kit-positive CSCs bearing the insulin growth factor (IGF)-1 receptor are more cardiopoietic.³⁴ In addition, it is clear that CSCs comprise subpopulations of vasculogenic and cardiopoietic cells.³⁵

C-Kit positive CSCs may be prepared from either surgical specimens of the atrial appendage³³ or endomyocardial biopsy samples of right ventricular septum.⁷ Collagenase-digested tissue yields c-Kit cells purified by antigenic panning, which are then expanded in culture, yielding therapeutic quantities of cells. After culture expansion, the degree of c-Kit expression may fall. As discussed further on, recognition of the presence of CSCs within the heart has offered a major insight into the mechanism of action of MSCs to stimulate myogenesis.²

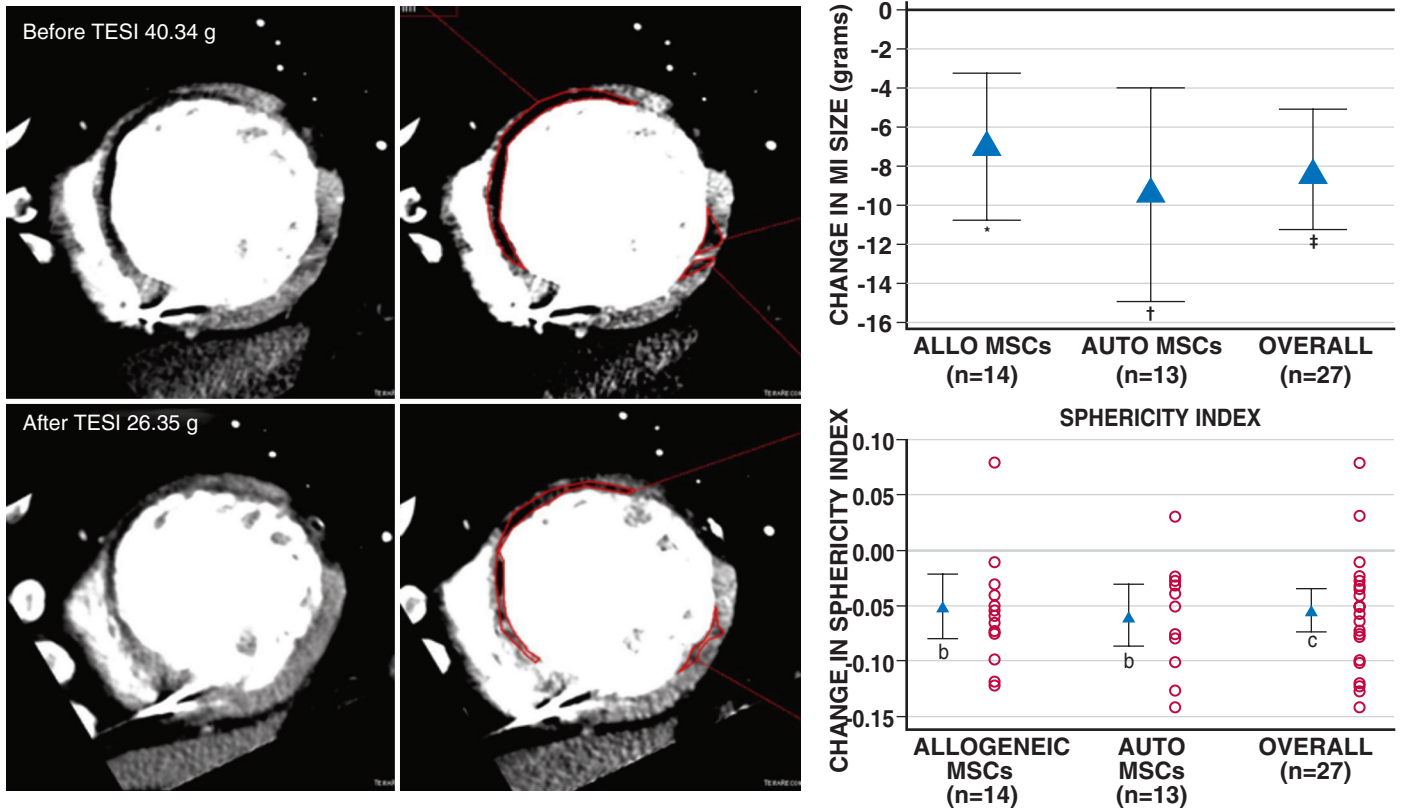

FIGURE 30-3 Results from the POSEIDON trial: After MI, transcatheter injection of stem cells, either autologous or allogeneic bone marrow–derived MSCs, reduced infarct size by one third, resulting in an improved sphericity index. TESI = transcatheter stem cell injection. (From Hare JM, Fishman JE, Gerstenblith G, et al: Comparison of allogeneic vs. autologous bone marrow–derived mesenchymal stem cells delivered by transcatheter injection in patients with ischemic cardiomyopathy: the POSEIDON randomized trial. *JAMA* 308:2369, 2012.)

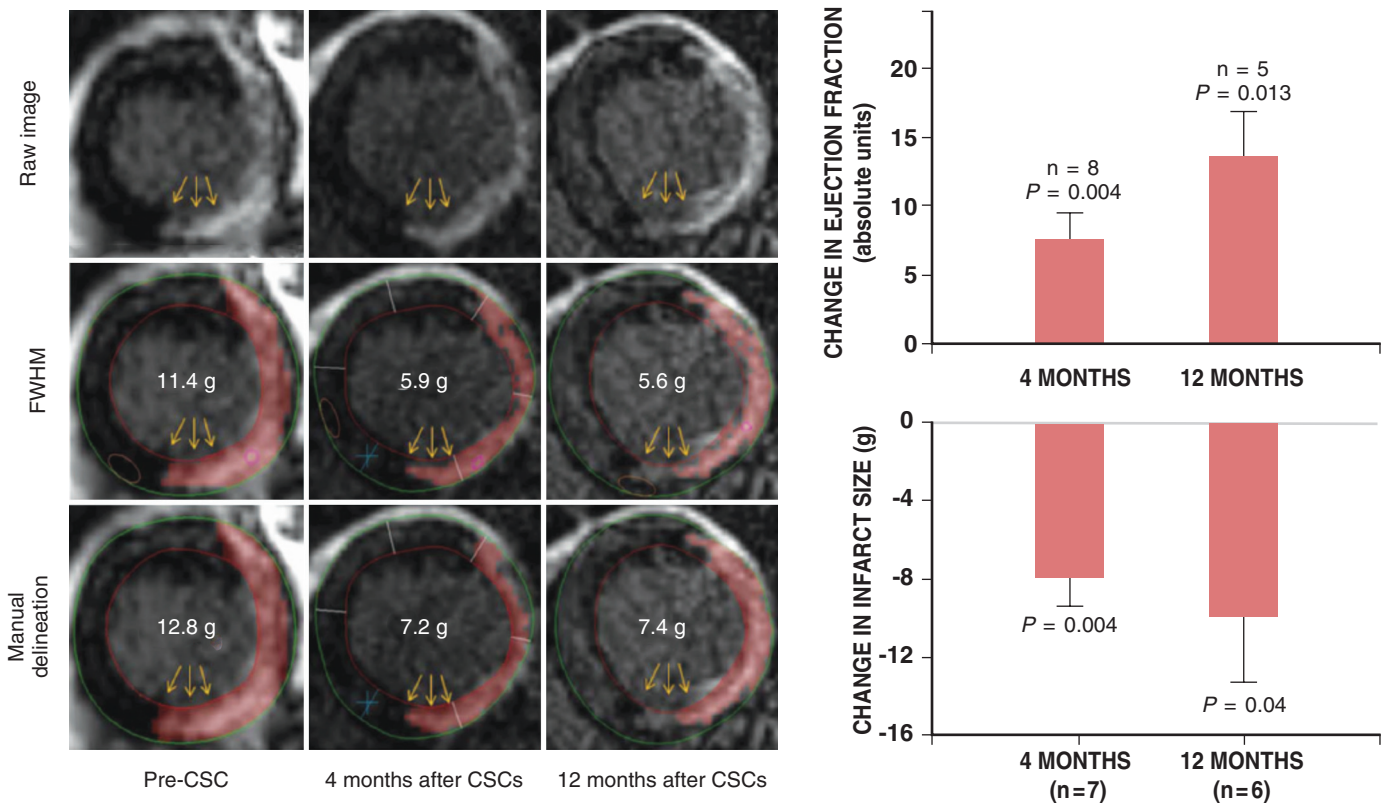

FIGURE 30-4 Results from the SCIPIO trial: In this study, autologous cardiac c-kit–positive cells were amplified from right atrial appendage biopsy material obtained at surgery. Subsequent intracoronary infusion of these CSCs produced reduced infarct size and increased ejection fraction. FWHM = full-width half-maximum. (From Chugh AR, Beache GM, Loughran GH, et al: Administration of cardiac stem cells in patients with ischemic cardiomyopathy. The SCIPIO trial: Surgical aspects and interim analysis of myocardial function and viability by magnetic resonance. *Circulation* 126(11 Suppl):S54, 2012; and Bolli R, Chugh AR, D'Amario D, et al: Cardiac stem cells in patients with ischaemic cardiomyopathy (SCIPIO): initial results of a randomised phase 1 trial. *Lancet* 378:1847, 2011.)

From a clinical testing perspective, another approach in cell-based therapy involves culture expansion of cell collections that have been called cardiospheres. These cell collections, which may be obtained from heart biopsy material, have been shown in the CADUCEUS trial (in patients with ischemic left ventricular dysfunction after a recent MI) to reduce infarct size. Further trials are anticipated for this approach.

Mechanisms of Action of Cardiac Stem Cells. After MI, the heart undergoes a process of remodeling that is proportional, in nature and extent of repair, to the size of injury (see Chapter 22).⁶ This process, involving collagen deposition, alteration in the collagen matrix, and loss of microvasculature, leads to a phenotype in which the myocardial scar thins and dilates, altering the shape of the entire ventricle. The scar and the changes in shape and contractile efficiency of the ventricular chamber become the substrate for sudden cardiac death and heart failure. Thus, although initial attention was focused on the capacity of a cell therapeutic to replenish new cardiac myocytes, new insights have suggested that some cell therapeutic strategies are effective owing to a combination of effects that, in addition to cell repopulation, also promote neovascularization³⁶ and reduction in the actual scar size.^{18,37} With regard to the latter, MSCs are demonstrated to have important antifibrotic effects, mediated by the release of matrix metalloproteases, that could contribute to reductions in tissue fibrosis.

Cardiomyocyte Regeneration. The ultimate goal of cell-based therapy is to replenish cardiomyocytes that are lost as a consequence of direct cardiac injury, which in turn initiates the process of scar formation and remodeling. Although the extent to which AWBM cells and MSCs differentiate into cardiomyocytes is controversial, these cell types have produced measurable improvements in the remodeling status of the ventricle.³⁸ Indeed, MSCs are demonstrated to be capable of both prevention and reversal of remodeling, and this is shown to be due, at least in part, to the differentiation of MSCs into cardiomyocytes and vascular elements (see Fig. e30-1). It should be noted however that this is highly controversial, and many studies reveal minimal to no cardiomyocyte differentiation. The latter has prompted the “paracrine” hypothesis that MSCs improve cardiac function in large part due to the release of growth factors and cytokines.^{1,39} On the other hand, experimental studies strongly support the capacity of CSCs to engraft and differentiate, and this has been shown in both small and large animal models.⁴⁰

The discovery and characterization of endogenous CSCs have greatly advanced the understanding of mechanisms of action of successful cell-based therapy. In a very important consequence of this insight, it recently became appreciated that bone marrow derived MSCs amplify the number and lineage commitment of endogenous c-kit–positive stem cells.⁸ Moreover, Suzuki and colleagues have shown the importance of cardiac c-kit–positive CSCs in the therapeutic response to MSCs in an animal model of hibernating myocardium.¹⁰ The ability of exogenous cells to stimulate endogenous cardiac repair was confirmed, using murine lineage tracing models, by Loffredo and co-workers.¹¹ Of note, this principle was tested in a porcine model of infarction in which human cardiac c-kit cells had greater efficacy when mixed with MSCs in reducing infarct size.⁴¹

The Importance of Cell-Cell Interactions. Perhaps one of the greatest insights in the field of regenerative cardiology is that of two or more cell types working together to achieve a desired therapeutic outcome. A key example derives from the observations by our group and other investigators that MSCs stimulate endogenous c-kit CSC recruitment.⁸ Moreover, these experiments have demonstrated the importance of cell-cell interactions. MSCs and c-kit–positive CSCs form gap junctions and N-cadherin–mediated mechanical connections (see Fig. e30-1). Thus the notion that cells exert important paracrine effect appears to have greater complexity. The formation of gap junctions between cells allows direct cell-cell communication, and of importance, gap junctions are likely able to transmit micro-RNAs.⁴² Other strategies using cell combinations as therapeutics can now be rationalized. For example, highly cardiopoietic cells may be combined with vasculogenic cells.⁴³

The insight that different cell types can work together to achieve successful tissue regeneration opens the major therapeutic opportunity of using cell combinations. The realization, for example, that cardiac tissue regeneration requires not only new myocytes but also appropriate small and large blood vessels, antifibrotic actions, and proper supporting elements makes it attractive to propose that a cardiopoietic cell could be combined with an endothelial precursor or an MSC. At a higher order, the concept that the cell therapeutic could

actually reconstitute missing CSC niches offers the highly attractive idea that niche reconstitution could create a sustainable and durable reparative milieu in the injured heart.⁴⁴

Clinical Applications of Stem Cells Ischemic Heart Disease

The totality of evidence now supports potential efficacy of cell-based therapy for a panoply of ischemic conditions, including acute MI (in which cell therapy prevents remodeling),^{17,45} chronic ischemic myocardium (reverses remodeling), hibernating myocardium (demonstrated in large animal models but not yet translated), and intractable angina pectoris. Each of these disease areas has undergone successful phase I and, in some cases, phase II study and, particularly in the case of acute MI, is poised to initiate phase III pivotal investigation. The clinical success of these approaches will be revealed only when pivotal trials, powered for hard clinical endpoints, are completed (see Table 30-1).

Nontraditional Clinical Indications

Although the main focus in the cell therapy field has been on ischemic heart disease, several other clinical scenarios warrant consideration as potential targets.

Idiopathic Dilated Cardiomyopathy
